ABSTRACT

AN INVESTIGATION OF FRESH AND HARDENED PROPERTIES OF CEMENTITIOUS GROUT MADE WITH COMBINED USE OF WASTE MARBLE POWDER AND FLY ASH

ÇINAR, Muhammet

Ph.D. in Civil Engineering

Supervisor: Prof. Dr. Mehmet KARPUZCU

April 2019

171 pages

The main objective of this thesis study is to investigate the effect of Waste Marble Powder (WMP) and Fly Ash (FA) on the rheology, workability, fresh and hardened properties of cementitious grout with respect to higher water/binder (w/b) ratios.

Due to the rapid increase in the demand for marble, which is a natural stone, the number of enterprises and factories related to marble sector is increasing. Depending on the capacity of these factories, mud, powder and pieces of marble waste are exposed; waste amount reaches up to 75%. Emptying the marble wastes to the usable agricultural land, the mixing of the very fine powdered part into the air and the water causes environmental pollution, has a negative effect on the health, covering the agricultural land in a long time and damages the soil and the products.

Fly Ash is a silica-based powdery substance originating from the flue-gas of thermal power plants. Because of its pozzolanic effect, it binds free lime from cement hydration. This feature caused by fly ash in concrete production are widely used, but the rapid increase in the demand for electrical energy in Turkey, inadequacy of existing plants necessitates the creation of new thermal power plants, which in our country annually about 13 million tons, which will further increase the amount of this waste it means.

The use of marble dust and fly ash from the solid wastes, which is an environmental problem in the world, in the improvement of the ground, which is a very important area of the construction sector, will provide the economic value of these wastes and will contribute to the prevention of environmental pollution by the removal of solid wastes. In this thesis; In order to contribute to the solution of the waste problem, it is aimed to use marble dust and fly ash in the production of cement based grout which is used for the treatment of soils. In the experimental study planned for this purpose, waste marble powder (WMP) and fly ash (FA) were replaced with cement; in this study, the fresh and hardened properties of cement based grout mixtures were

investigated by experimental study. The investigation of the effects of these mixtures on the ground by model experiments was excluded.

Four series of mixtures were prepared for the production of cement based injection mortars. In the first series prepared, 5, 10, 15, 20, 25% by weight of the marble was added to the cement. In the second series 25% (fixed) by weight of fly ash, 10, 15, 20, 25, 30% of the amount of waste marble dust was added to the cement. In the third and fourth batch mix, 20% by weight of clay is added to the whole mixture ratio provided that the ratios in the first two series remain constant. The ratio of water to the binder in each series was chosen as 0.75, 1.00, 1.25, and 1.5. A total of 48 (forty-eight) different injection mixtures were prepared with these materials and ratios. In each of the mixtures, a series of tests, such as plate cohesion, marsh funnel flow time, mini slump flow diameter, and cylindrical rotating rheometer, were carried out, including freshness and rheology tests. Specifically prepared series of 432 cylindrical specimens with a diameter of 5.5 cm, 11 cm in height, with three and four series identified; unconfined compressive strength test (UCS) were performed on 3, 7, 28 days. In each series, control sample was prepared by considering water-binding ratios. Control samples ingredient included first and second series water and cement, thirth and fourth series water, cement and clay. No additives were added to the cntrol samples.

The test results were compared with the control samples and the literature; It has been concluded that mixtures of cement based grout prepared using waste marble dust and fly ash can be injected and used in the treatment of weak soils.

Bu tez çalışmasının temel amacı, Atık Mermer Tozu (WMP) ve Uçucu Kül (FA) ikame edilmiş çimento bazlı enjeksiyon karışımlarının yüksek su / bağlayıcı (w / b) oranlarında reolojik, işlenebilirlik, taze ve sertleştirilmiş özelliklerini üzerindeki etkisini araştırmaktır.

Doğal taş olan mermer talebi hızlı artışa bağlı olarak mermer ile ilgili işletme ve fabrika sayısı da artmaktadır. Bu fabrikaların kapasitesine bağlı olarak çamur, toz ve mermer atıkları ortaya çıkmaktadır; atık miktarı % 75'e kadar ulaşmaktadır. Mermer atıklarının kullanılabilir tarımsal alanlara boşaltılması, çok ince toz şeklinde olan kısmının havaya ve suya karışması çevre kirliliğine neden olur, sağlığa olumsuz etki yapar, uzun sürede tarım arazilerini kaplayarak toprağa ve ürünlere zarar verir.

Uçucu Kül, termik santrallerin baca gazından kaynaklanan silika esaslı toz halinde bir maddedir. Puzolanik etkisi olduğu için çimento hidratasyonundan açığa çıkan serbest kireci bağlar. Bu özelliği nedeni ile uçucu kül, beton üretiminde yaygın olarak kullanılmaktadır, ancak Türkiye'de elektrik enerjisine olan ihtiyacın hızla artması, mevcut santralların yetersiz kalması yeni termik santralların kurulmasını zorunlu kılmaktadır, bu da ülkemizde yıllık yaklaşık 13 milyon ton olan bu atık miktarının daha da artacağı anlamına gelmektedir.

Günümüzde tüm dünyada çevresel bir sorun olan katı atıklardan mermer tozu ve uçucu külün inşaat sektörünün çok önemli bir alanı olan zeminin iyileştirilmesinde kullanılması, bu atıkların ekonomik değer kazanmasını sağlayacak, katı atıkların bertaraf edilmesi ile çevre kirliliğinin önlenmesinde önemli katkıda bulunacaktır. Bu tez çalışmasında; atık sorunun çözümüne katkıda bulunmak için mermer tozu ve uçucu külün zeminlerin iyileştirilmesinde kullanılan çimento esaslı enjeksiyon harcının üretiminde kullanılması amaçlanmıştır. Bu amaçla planlanan deneysel çalışmada atık mermer tozu (WMP) ve uçucu kül (FA) çimentoya ikame edilmiş; yüksek su / bağlayıcı (w / b) oranlarındaki çimento esaslı enjeksiyon karışımının reolojik ve işlenebilirlik gibi taze, basınç dayanımı gibi sertleştirilmiş özelliklerini

deneysel çalışma ile araştırılmıştır. Bu karışımların zemine yapacağı etkilerin model deneysel ile araştırılması kapsam dışı bırakılmıştır.

Çimento esaslı enjeksiyon harçlarının üretiminde dört seri karışım hazırlanmıştır. Hazırlanan ilk seride çimentoya ağırlıkça %5, 10, 15, 20, 25 oranında atık mermer tozu ilave edilmiştir. İkinci seride çimentoya ağırlıkça %25 (sabit) oranında uçucu kül, %10, 15, 20, 25, 30 oranlarında atık mermer tozu ilave edilmiştir. Üçüncü ve dördüncü seri karışımında ise ilk iki serideki oranlar sabit kalmak koşulu ile tüm karışım oranına ağırlıkça %20 oranında kil eklenmiştir. Her seride suyun bağlayıcıya oranı 0.75, 1.00, 1.25, ve 1.5 olarak seçilmiştir. Bu malzemeler ve oranları ile toplam 48 (kırk sekiz) farklı enjeksiyon karışımı hazırlanmıştır. Karışımın her birinde taze halde iken işlenebilirlik ve reoloji testlerini içeren plaka kohezyon, marsh hunisi akış zamanı, mini slump akış çapı ve silindirik dönen rheometre gibi bir dizi test yapılmıştır. Özellikleri belirlenen seri üç ve dört karışım ile çapı 5.5 cm, yüksekliği 11 cm olan 432 adet silindir numune hazırlanmış; 3, 7, 28 günlerde basınç deneyleri yapılmıştır. Her seride su / bağlayıcı oranları göz önüne alınarak kontrol numunesi hazırlanmıştır. Kontrol numunelerinin içine seri bir ve ikide sadece su ve çimento, seri üç ve dörtte çimento, kil ve su katılmış herhangi bir katkı maddesi ilave edilmemiştir.

Deney sonuçları kontrol numuneleri ve literatür sonuçları ile karşılaştırılmış; atık mermer tozu ve uçucu kül kullanılarak hazırlanan çimento bazlı enjeksiyonun karışımının zayıf zeminlerin iyileştirilmesinde enjekte edilebilir ve kullanılabilir olduğu kanaatine varılmıştır.

Anahtar Kelimeler: Çimento enjeksiyonu, Atık mermer tozu, Uçucu kül, Reoloji, İşlenebilirlik, Taze ve Sertleşmiş özellikler, Soilcrete

To My Parents

ACKNOWLEDGEMENTS

In the name of Allah, the most benevolent, the most merciful. First of all, I wish to record immeasurable gratitude and thankful fullness to the one and the almighty creator, the Lord and sustainer of the universe, and the mankind, in particular. It is only through His mercy and help that this work could be completed, and it is ardently desired that this little effort be accepted by Him to be of some service to the cause of humanity.

This dissertation has been completed under the guidance of my advisor, Prof. Dr. Mehmet KARPUZCU. I dedicate the greatest and sincere thanks to my supervisor for his advice, guidance and help throughout the preparation of this work.

I would like to thank to Prof. Dr. Hanifi ÇANAKCI and Prof. Dr. Ömer ARIÖZ for their helps and valuable suggestion.

Also, I would like to thank to Res. Assist. Mehmet SAKİN, Res. Assist. İbrahim Halil DEGER, and Assist. Prof. Dr. Mehmet Eren GÜLŞAN for supporting me during my research.

My thanks are also expressed to my parents (Hüseyin ÇINAR and Şefika ÇINAR) for their appreciable toil and supports upto now.

I would like to extend special thanks to my wife, Zamire ÇINAR, my sons, Hüseyin ÇINAR and Said ÇINAR for helps, patience and encouragement during this work.

Finally, I would also like to specially thanks to everyone who I cannot remember and tell their names and who have big toils on my success and life upto now.

CHAPTER 1

INTRODUCTION

1.1. Overview

Cement Based Grout (CBG) is a widely used method for many applications in the geotechnical area. Some examples of CBG applications are suspension grouting, emulsion grouting, solution grouting, compaction grouting, permeation grouting, displacement grouting and replacement grouting. The rheological and permeability properties of the CBG are straightly involved with the penetrability and pumpability in cracks and soil voids.

Because of the need for underground improvement (e.g. metro, tunnel, canal, basement etc.) over the last twenty years, practice of grouting method in solving problems related to groundwater leakage, insufficient foundation soil and precision existing construction have been commonly applied in the infrastructure construction works in around the world. Permeation grouting by injecting CBG into the ground via a pressure system, e.g. pump, was found mostly applied in the construction industry for decreasing leakage impact induced by diggings in permeable media, e.g. sand of high permeability and improving the steady and bearing resistance of soil in diggings and foundation works, separately.

Because of the complication of the rheological characters (e.g. viscosity and yield stress) of CBG and its uncertain flow movement (i.e. injectability or groutability) in permeable media undersoil, specially, in the regional sandy soil usually found with the high ingredient of fines normally used by using chemical grout or superfine cement grout overseas, the influence of permeation grouting using standard Portland cement with high w/c rate in excess of 3.0 by some regional researcher is not clear. For this reason, it appears that it is still substantially a trial and error process in the present practice, particularly in the local construction industry. If it is not satisfactorily completed, it could lead to wastege or failed performance (e.g. weak water impermabilty) of the soil improvement work.

In the present situation of the grouting, the movement of a viscous fluid injected from the borehole into the ground was examined by considering the laminar flow from inside a cylindrical or spherical cavity into the mass of granular soil completely homogeneous.

In accordance with Tomiolo (1982), these 2 current flow types (Raffle and Greenwood, 1961) consider the flow of viscous fluids through the soil follows the similar laws ruling the flow of water, all worths (e.g. coefficient of permeability to grout, k_G) being amplified proportionally to the rate of grout viscosity to water viscosity as displayed in Eq. (1.1).

It is the idea of the author that such importance may not be suitable for CBG with water/cement ratio (w/c, by weight) below 1.5 in view of the important Bingham's fluid characteristics possessed by these CBG mixes and also the very high injection pressure applied in the CBG permeation grouting works, which may effect the validity of Darcy's law.

$$\frac{k}{k_G} = \frac{\eta}{\eta_w} \quad (\text{after Muller-Kirchenbauer, 1968}) \quad (1.1)$$

Where, η_w = viscosity of water, Pas, η = viscosity of Newtonian grout, Pas ($N.s/m^2$), k = permeability of soil to water, m/s, k_G = permeability of soil to grout, m/s

For improve the practice of CBG using the existing flow models in the local construction industry, proper understanding of the characteristics of CBG, including the effects of the handling process to the viscosity measurement of CBG and grout flow properties taking into account the effect of high injection pressure on the coefficient of permeability for CBG (k_G) in permeable area, i.e. the validity of constant k_G based on Darcy's law, existing flow models require a default value is needed.

Literature review and regional application reveals the limited rheology work for CBG in published research studies and uncertainties regarding CBG implementation like:

- Porous flow of Bingham's fluid;

- Rheological characteristics (e.g. yield stress and viscosity) of CBG with w/c between 0.6 and 1.5 not available in research work in the past, specially for the normal Portland cement mostly used in the local construction industry, taking into importance of dependence on time and shear history dependence on several mixing and measurement programs;
- Effect of injection pressure in flow properties of CBG in permeable area.

1.2. Use of Grouting for Ground Engineering

Due to the rapid development of underground urban infrastructure, the utilization of grouting has been more favored in last decade, underground space for commercial (e.g. carpark) and civil protection building (e.g. storage and shelter) and underground facilities (e.g. tunnel system and common services channel) uses and the need in place control during construction. The grouting could be utilized to develop the construction area against potential construction problems as follows:

- To decrease the porosity of ground for reduce leakage effect
- To strengthen soils to make better its resistance in against liquefaction effect, excavation stability and load carrying capacity.
- Increasing the stability of existing buildings
- Fixing the soil to facilitate tunnel opening or shaft excavation.
- Create an obstacle or cut against water or contaminant flow on the soil.

1.3. Rheology of Grout

Rheology is the examination of the materials flow. The major characteristics of grouts are viscosity, stability and setting time. The measured stability properties contain pressure filtration and bleed. Bleed is the free water amount that improves with duration at a grout column top at rest, expressed as its total volume percentage. If the bleeding is below five percent after two hours, a mortar is considered stable. Pressure filtration is a leakage measurement under pressure. The pressure filtration coefficient is a measure of how much water is taken from of a sample under pressure in a given time period.

Grout requires setting time for hardening. CBG usually setting within four to twenty-four hours which depending on the additives used. For chemical groups that can be adjusted very quickly in minutes, setting or gel time can be critical. Viscosity (μ) is defined by Newton's law of viscosity, which is the proportionality factor that relating the shear resistance (τ) in a fluid to the speed gradient (dv/dz), it represents the ratio at which a fluid layer moves relative to an adjacent layer.(Eq. 1.2)

$$\tau = \mu \cdot dv/dz \quad (1.2)$$

The above equation hold for laminar flow. The SI unit for viscosity is the pascal-second (Pa.s). The viscosity μ is also called the dynamic viscosity or absolute viscosity. When dynamic viscosity is divided by mass density ρ , it becomes the kinematic viscosity (v). (Eq. 1.3)

$$v = \mu / \rho = (\mu \cdot g) / \gamma \quad (1.3)$$

The units of kinematic viscosity are square meters per second. Another unit name which may be used is the centistoke (cSt) where $1 \text{ cSt} = 10^{-6} \text{ m}^2/\text{s}$. For turbulent flow dynamic eddy viscosity η is used.(Eq. 1.4)

$$\tau = (\mu + \eta) \cdot dv/dz \quad (1.4)$$

Turbulent flow is important as far as maintaining the stability of the grout during pumping is concerned. When it comes to evaluating the extent of grout penetration into the ground, laminar conditions are generally assumed. The transition from laminar to turbulent flow is usually described in terms of dimensionless Reynold's number Re . (Eq. 1.5)

$$Re = (\rho v L) / \mu \quad (1.5)$$

v is the flow velocity and L is the characteristic length. Normally, a grout must have low viscosity, a controllable setting time and high strength when it enters the ground. It should not be toxic, permanent and inexpensive.

Viscosity of grout can be estimated directly or indirectly. Rheologic properties of grouts can be calculated by using several test methods. Some of them are given below.

1. Viscometer

2. Marsh cone test
3. Plate cohesion test
4. Mini slump test.

In Newtonian fluid the shear stress varies proportionally to the velocity gradient dv/dz . A fluid which has a non-linear relationship between dv/dz and shear stress is classified as non-Newtonian. Bingham body is not a fluid, but rather a visco-plastic solid. Nevertheless the term Bingham fluid. The rheological attitude of a Bingham body is expressed by;

$$\tau = \tau_0 + \mu(dv/dz) \quad (1.6)$$

The initial yield stress (τ_0) is also called rigidity. (Eq. 1.6) Some engineers refers to it as cohesion or flow limit. Water behaves as a newtonian fluid. Clay particles in suspension represent a non-newtonian substance. A cement or clay grout might be almost as Bingham body is treated.

1.4. Waste Marble Powder(WMP), Fly Ash (FA) and Soilcretes Properties

CBG is mixed of water, cement and admixture. For CBG mix design, different range of water-cement (w/c) ratio can be utilized. For the applications of permeation grout, w/c ratio of CBG range between 0.5 and 1 (Danot and Derache, 2007). The w/c rate of injectable grout ranges from 1 to 2. Also, the grout should be similar to the liquid that can be injected into the rock and soil (Baltazar et al., 2012). CBG mixes have usually water-cement ratios of 1.00 by volume.

Mineral and chemical admixtures are used to develop the properties of CBG like durability, permeability, rheological and fresh properties. Adding mineral admixtures to the CBG at different amount modify the rheological and fresh properties of injections. For various types of grout applications, various additions (Cement kiln dust, silica fume, rice husk ash, metakaolin and bentonite) have been applied (Miltiadou, 1991; Ruggiero, 1984; Weaver, 1990).

Some recent studies showed that additive, like rice husk ash, have increased the durability, long-term performance and workability of CBG mix (Sonebi et. al., 2013; Rosquoe et al., 2003). Consequently, the additives usage in CBG applications reduce the charge of the application but increment the flowability and the strength.

Marble is a very important material for construction, particularly for decoration reasons. %25 percent of marble turns to powder and dust due to shaping, polishing, and sawing. Turkey has 40 percent of the world's total marble and produces 7 million tons of marble were manufactured every year. Five thousand processing factories are used for marble production in Turkey. It is clear that these waste products reach millions of tons; so it is too difficult to store this amount of wastes (Alyamaç and Ince, 2009; Pooja and Prof, 2014).

FA is a divided siliceous tailing from the burning up of powdered coal and can be used an admixture. Fa has the same fineness like Portland cement (PC). It can also react easily chemically with cement. Also, the average annual FA production in Turkey has about 13 million tons and half of it was utilized.

The disposal of WMP and FA are one of the most environmental concerns all over the world nowadays. On the other hand, WMP and FA can be used to increase the fresh properties of cementitious grout.

WMP is used like a complementary cement based material in the concrete. Earlier researches concluded that maximum 10-15 percent of WMP can be conveniently mixed into the concrete without negatively impacting the durability, hardness and strength of the resulting concrete (Shirule et al., 2012; Aliabdo et al., 2014). Another researches investigated the usage of WMP as a cement substitution. Also, Study showed that combining of WMP in self-compacting concrete (SCC) with concrete reduce the splitting tensile strength, compressive strength, bulk weight, slump flow, ultrasonic pulse velocity, porosity and cost (Aliabdo et al., 2014).

Usually, the percentage of FA usage is 10-35% in concrete(Yao et al., 2015). The usage of FA in concretes and SCC have also been investigated and have been well developed in the last decade(Uysal and Yilmaz, 2011). On the other hand, there is limited knowledge available concerning the fresh characteristics of cement based grout containing FA. The replacement of Portland Cement with FA is important for decreasing the viscosity, increasing passing ability and flowability of cement based grout materials(Sadati et al., 2016). The aim of this experimental study is to research the impact of water-binder (w/b) rate (1.00) and different percentage of WMP, FA and WMP+FA content on the workability, fluidity, and rheological characteristics of CBG.

1.5. Objectives of The Thesis Study

The goal of the thesis study is to research the effect of Waste Marble Powder (WMP) and Fly Ash (FA) on the rheology, mechanical and workability characteristics of cement base grouts with respect to higher water/binder (w/b) ratios. Based on this modeling process, following studies are aimed;

- ✓ To investigate the effect of using WMP and FA as an additive on rheological properties (yield stress and viscosity) of cement base grout at different range of w/b ratios that are generally used for jet grouting applications.
- ✓ Also to find the effect of WMP and FA on cement base grouts depending on workability properties such as mini slump diameter, marsh cone flow time and plate cohesion meter.
- ✓ Then, to evaluate the impact of WMP and FA on compressive strength of soilcretes obtained by mixing WMP, FA, cement, clay, and water at different w/b ratios ranges.
- ✓ In addition, to examine the bleeding features of grout mixtures prepared by mixing WMP, FA, cement, clay and water at different w/b ratios ranges.
- ✓ Finally, to compare the results with control samples and literature to show the injectability, workability and usability of the cement base grout obtained by using WMP and FA, which is waste materials.

1.6. Organization of The Thesis Study

The organisation of the thesis study was presented as following;

In Chapter 1: general background and introduction of the study were given. General information about the grouting techniques, grouting materials cement base grouts, rheological and mechanical properties of the cement base grouts were discussed in this chapter

In Chapter 2: detailed literature informations related with rheological and mechanical properties of cement base grouts were given and discussed.

In Chapter 3: detailed overview and theoretical background of cement base grouts were investigated and the methods and models were discussed.

In Chapter 4: experimental study of rheological and workability properties of cement base grouts mixing with WMP prepared for this study were presented. And also test results obtained from the thesis study were discussed.

In Chapter 5: experimental study of rheological and workability properties of cement base grouts mixing with WMP and FA prepared for this study were presented. And also test results obtained from the thesis study were discussed.

In Chapter 6: evaluation of unconfined compressive strength, stability and failure criteria of the soilcretes samples obtained from mixing of cement base grout with WMP and FA and clay soil were investigated and test results were given and debated.

In Chapter 7: conclusions and recommendations extracted from the thesis study were explained.

CHAPTER 2

LITERATURE SURVEY

2.1 Studies on Rheological Properties of CBG

The rheological characteristic (e.g. viscosity and yield stress) of grout with the inclusion of different influence types like as stability (bleeding), mixing duration, additives and the degree of saturation have been worked by a lot of researchers until now. Although, the knowledge got from all these works are shown more intensive in the characters of the solution grout, microfine cement grout or ordinary CBG with additives (e.g. bentonite, etc.) owing to weak penetration of arrant CBG because of its short setting time and high viscosity, and the grout mixtures considered in these works are found not to cover the proper range of CBG mixtures, i.e. water /cement = 0.6 to 1.5, for efficient implementation of penetration grouting in sand using ordinary Portland cement as accepted in the experimental program of the present work. Some of the findings / comments obtained from previous studies are summed up as below.

Cambefort (1964) clarified that CBG has good-defined shear stress that improves directly later mixing and is qualified by its viscosity function.

Klein and Polivka (1958) schematically interpreted the cement grout stages after mixing as dormant, hardening and setting with a grout strength increasing with curing time nearly in function of power or exponential.

Caron (1963) entitle CBG as Bingham's grouts, as owning hardness and viscosity at the same time, both increment with time and displacement could only start beyond a specific pressure or so called yield stress.

Raffle and Greenwood (1961) improved a graphical relationship between the rheological properties of grout (Figure 1.1) and its capacity to pass on the soil and remarked that injection of fresh cement grout is controlled by shear strength and viscosity in order of in the early and later phases. Significant increases in shear strength and viscosity have been reported for the CBG not exceeding 0.6, as shown in Figure 1.1 with the water/cement ratio (w / c).

Little John (1975) made an observation that a w/c rates between 0.4 and 0.45 give a grout with adequate fluidity to be pumped and placed easily in a small diameter borehole and yet keep enough continuity and strength after injection to act as a strengthening area. He reported a rapid increment in shear strength and viscosity for CBG with w/c rate below from 0.9 which is different from the rate of 0.6 noticed by both Burgin (1979) and the author.

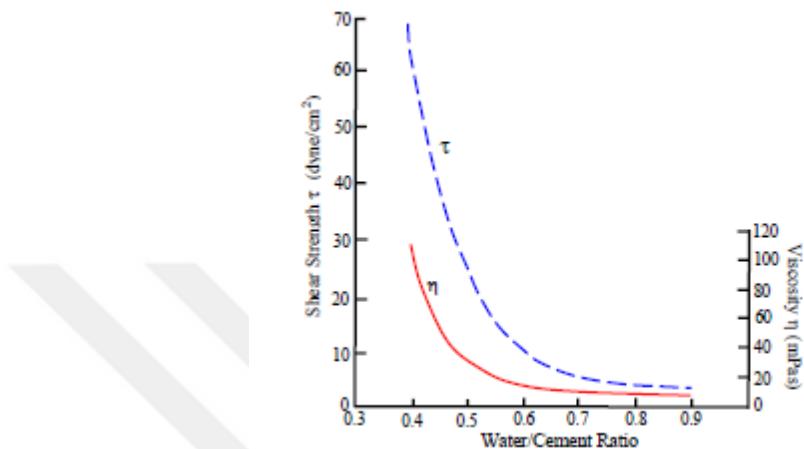

Figure 2. 1: Shear Strength and Viscosities for Cement Pastes with Different w/c Rate (after Raffle and Greenwood, 1961)

Deere (1982) were classified as cement grout as fixed grout due to bleeding not passing over five percent after two hours from finishing of mixing and commented that little amount of bentonite appears to be sufficient, preferable to decrease bleeding and sedimentation but not large enough to develop the penetrability and pumpability.

Banfill (2003) indicated that a mixing time of about five min is enough in order to get stable characteristics for both the plastic viscosity and the yield value. On the other hand, the blended grout volume is unknown.

Lombardi (1985) analyzed the flow terms of a mixture through a smooth stone crack and finalized that the yield stress detects the maximum distance the grout can reach and the viscosity determines the flow ratio and for this reason the time essential to fulfill the injection.

Paoli et al. (1992) debated the basic finding on CBG and commented that penetration is controlled by the particles size more than by yield stress and the grout viscosity ingredients. The grout penetrability can be developed by decreasing the size of the

cement particle grains and development the grout's rheological characters, increment the stability under pressure percolation and decreasing the yield stress.

Vipulanandan et al. (1992) examined the CBG characteristics and grouted sands with additives and stated that the maximum particle size should not exceed 1/3 to 1/10 the void size to penetrate a formation at a reasonable rate and pressure.

Helal & Krizek (1992) stated the orientation of the porous structure in CBG sand indicated that porous structure injected with a CBG is a w/c rate function and the suspended materials sedimentation attitude.

Shroff et al. (1996) studied the microfine cement dust (MCD) grouts rheological characteristics and reported that MCD grout could penetrate into the permeable medium sand and also sand have to permeability value, $k = 7.89 \times 10^{-3}$ cm/sec. In addition, He stated that MCD grout possesses not only penetration capability in medium to fine sand comparable to many chemical grouts but also to provide higher adhesion strength to the mass in the grout.

Perret et al. (2000) investigated the impact of the sand saturation degree on groutability and finalized that the grout spreading through permeable area is affected not only by the particle size dispersion of the cement and soil, the water penetrability of the soil and rheological properties of the grout but also the sand saturation degree. The grout water dilution is higher in the unsaturated soil than in the saturated soil, where the grout may be replaced by the water, resulting in a grout layer mixed and diluted with water. In the case of unsaturated sand, the suction resulting from capillary pressure and the non-continuous aqueous medium of the pore water in the soil are led to further water dilution in the unsaturated sand case.

2.2 Marble Powder (MP)

Marble is a very important material for construction, particularly for decoration reasons. 25 percent of marble turns to powder and dust due to shaping, polishing, and sawing. The wastes of the marble factory have turned into a main environmental issue onwards the early of the 1990s. This problem is not only a local issue but also direct anxiety for all at of countries. In many countries, like Turkey, Italy, Iran, India, China, Brazil, Spain, Portugal, South Africa, USA, Pakistan, Finland, and Egypt, export the marble products, many other countries, like Germany, Japan, South Korea, and Taiwan, import them (Alyamac et al., 2017). Turkey has forty percent of the world reserves of marble, and the storage of waste generated during production is of

great significance. Turkey has approximately marble reserves of 3.872 million m³, of which close to $125 * 10^3$ t/year are produced in Afyon City. (Singh et al., 2019). Five thousand processing factories are used for marble production in Turkey. It is clear that these waste products reach millions of tons; so it is too difficult to store this amount of wastes (Alyamac and Ince, 2009).

2.3 Fly Ash (FA)

Fly ash is a waste product of coal-fired thermic power plants and has been successfully used as embankment material for road construction projects or a structural filler around the world. Compared to the classic soils used in the filling, fly ash has a matchless engineering material. When dried, the fly ash is incompatible and is considered by many to be a dusty disturbance. If it is saturated, fly ash becomes an uncontrollable mess. However, as with most fine-grained soils, fly ash can be easily used and compressed in more moderate-medium contents and exhibits some amount of cohesion.

The use, storage, and disposal of fly ash produced by coal-burning power plants continue to be the main problem in all over the world. Although it is used in significant quantities in a variety of applications, and especially as a substitute for cement in concrete, large quantities are not used and must be disposed of at high cost in waste collection facilities.

Effective utilization of waste materials decreases the need for large disposal areas, while providing a cheap mineral resource for construction applications. Geotechnical engineering became a key profession in evaluation of the engineering performance of byproduct materials, and in finding new applications.

2.4 The Previous Studies Related with Marble Powder and Fly Ash

Various research studies have been conducted to find the usability of WMP and FA. It has been concluded from these studies that WMP can be beneficial for low cost construction material as pozzolanic additive material.

Shirule et al. (2012) replaced the cement with MP and researched how MP impacts the mechanical characteristics of the concrete. They finalized that the marble powder replacement percentage was 10% and the compressive strength of 28 days increased by 17% and the tensile strength was increased 11.5%.

Uysal and Sumer (2011) examined the impacts of different additives, with the inclusion of marble powder, on the self-compacting (SCC) concrete performance. MP replacement were used in 10, 20, and 30% cement percentage. In compression tests performed on days 7, 28, 90 and 400, the control sample performance was matched with the best 10% MP replacement. On the 400th day, the compressive strengths of samples replacement percentage of 10, 20, and 30 MP were measured to be 97.6, 96.8 and 93.4 MPa, while the control sample was found to be 100 MPa. The loss of UCS (according to the control sample) was recorded as 12.3%, 20% and 8.5% in samples with 10%, 12 and 20% marble powder replacement in 10% magnesium sulfate solution, respectively.

Uysal and Yilmaz (2011) studied the impacts of various mineral additives on SCC performance. Samely to Uysal and Sumer (2011), they substituted cement with MP percentage of 10, 20, and 30. On day 90, they found the UCS at 82 MPa in the control sample and 84, 81, and 80 MPa in samples changed with MP percentage of 10, 20, and 30, respectively. In addition, they performed cost analysis according to the compressive strength of 28 days, obtaining 0.52, 0.48, and 0.47 US\$/MPa/m³ for replacement sample with 10, 20, and 30% MP and US\$0.58/MPa/m³ for the control sample.

Rana et al. (2015) examined the usage of marble slurry (MS) in concrete manufacture. For this reason, 5, 10, 15, 20 and 25% MS were replaced instead of cement. On days 7, 28 and 90, the UCS of the control sample was 36, 43 and 51 MPa, respectively. The strength of the specimen containing 5% MS was 50, 42.5 and 35.5 MPa. The UCS reduces with an enhancement replacement percentage of MS on all 3 test days. On days 90, 28, and 7 the flexural strength was 6.8, 6.5, and 5.4 MPa, respectively, in the control specimen, and almost 6.5, 6.4, and 5.3 MPa, respectively, in the sample replacement with 5% MS.

Rodrigues et al. (2015) cement was replaced by 5, 10 and 20% MP and investigated the concrete mechanical characteristics. To this end, they produced a no chemical complement, a hyper plasticizer supplement, and a superplasticizer complement. Among the mechanical characteristics, the ultrasonic pulse rate was the least sensitive to the substitution rate and the wear resistance was changed to the maximum rate of 20% substitution (decreased by 4.4%).

Rodrigues et al. (2015) claimed that the replacement of MP compensated for decreased compressive strength. MP substitution rate of up to 10% did not find a decrease in compressive strength; But, at a 20 replacement percentage, the compressive strength was reduced by 25%. From the UCS on days 7, 28, and 56 in every group, they concluded that UCS is a reducing function of the MP replacement percentage. The largest recorded decrease was 33.9%. Accompanied by the rejected compressive strength, they measured a decrease in the 28 day splitting tensile strength, which was incremented to a maximum of 30.9%. These rates were proximate from the graphics shown in their experiment.

Aliabdo et al. (2014) substituted natural sand and cement with MP and studied how the replacement influenced the characterizes of concrete. They contain MP at replacement percentage of 5, 7.5, 10 and 15.

Rodrigues et al. (2015) found that replacing 15% of sand or cement with MP didn't importantly impact the ultrasonic pulse ratio. In addition, substituting 10% of the sand with MP incremented the UCS of concrete by 14%. In the low water/cement range, the strength was increment by 22%. In contrast, in the example substituted with 15% MP, the compressive strength was the same to or less than that of the control sample, but the steele concrete bond strength (adherence) was developed. Adhesion showed a maximum improvement in the 10% substitute specimen.

Aliabdo et al. (2014), it was also found that 10% of natural sand or cement substituted MP with a 15% increment in splitting tensile strength. Raising the rate of replacement percentage to 15% decreased the tensile strength but gave better performance than the control specimens. In the study, specimens with low water/cement rates have consistently ensured good results.

Ergun (2011) substitute the cement with MP percentage of 5, 7.5 and 10 and found the characters of the ordinary concrete.

Corinaldesi et al. (2010) found that MP served as filler. Substitute the 5% MP increased the flexural and compressive strength of the concrete by 5% and 12 %, respectively, and reduced the porosity. The addition of superplasticizers has had a positive impact on a small percentage of MP substitute. The MP improved the

mechanical characteristics of the concrete at a substitute rate of 5% and incremented the compressive strength because of the filling effect.

Topçu et al. (2009) studied the impacts of MP on the mechanical characteristics of SCC. They substituted cement with MP at rates of 30%, 40%, 50%, and 60%. Too much amount of cement was substituted with MP, the bending and compressive the concrete strengths reduced. MP substitute at 300 kg/m³ decreased the splitting tensile and compressive strengths by 47 and 51%, respectively. In accordance with these researchers study, increasing the rate of MP cause decreasing in the slump flow (mm).

Belaidi et al. (2012) researched the impacts of MP and natural pozzolan on SCC. They made two experiments; one was substituted portland cement with puzzolana at the percentage of 5 to 25%, while the other was prepared with MP at a percentage of 10 to 40%. In both experiments, a substitute rate of 40% reduced the compressive strength by 50% and increment the slump value.

Gesoglu et al. (2012) examined the mechanical characters of concrete with various substitute rates of MP. According to the control samples, the slump values of samples manufactured with 5, 10, and 20% replacement rates were reduced, and the setting time was an enhancement function of MP rate. The UCS of 28 days was 13.46% lower in the specimen with 20% MP rate compared to the control specimen. The UCS of 90 days changed significantly at 5% replacement but decreased by 3% when the replacement rate to 10%. Also, replacement with 5 and 10% MP decreased the splitting tensile strength by 14 and 5.2%, respectively, according to the control specimen. These data are taken from the graphs shown in the report of Gesoğlu et al. (2012).

Elyamany et al. (2014) studied MP as filler material in SCC and examined the physical and mechanical characters of the modified product. For this purpose, they replaced 7.5%, 10%, and 15% MP into a mixture of 400 kg/m³ cement and 10% MP, and a preparation of 500 kg/m³ cement. The 7-day UCS of the mix made with 15% MP and 15% silica fume were almost 36.5 and 31 MPa, respectively. The compressive strengths increment to 47.5 and 46.5 MPa, after 56 days. They deduced that the fill type greatly affects the bleeding and segregation rates. Especially, both values are decreased by non-pozzolanic filler material.

Gencel et al. (2012) researched the usability of MP in concrete pavement blocks. The cement types prepared two series samples based on 32.5 and 42.5 and substituted the fine aggregates with 10%, 20, 30 and 40% MP. Both series also, they found that as the rate of MP incremented, the bulk weight, splitting tensile strength, and compressive strength all reduced. When the 28 day UCS between the test and control specimen were cross-checked, the compressive strength was reduced by 94.3, 91.7, 86, and 76.4% at MP substitution rates of 10, 20, 30, and 40%, respectively.

Gesoglu et al. (2012) indicated that the cement substitute with MP at 20% or higher negatively impacts the mechanical concrete properties of concrete. These different outcomes are opinion to be reasoned by the various C₃A substances of the cement used in the different experiments. Uysal and Sumer (2011), Gesoglu et al. (2012), Uysal and Yilmaz (2011), Ergun (2011), accordingly, the appropriate concrete change rate was determined as 5%. There are two likely comments for this impact. First, the silica in the MP reacts with the Ca(OH)₂, which results from the hydration reaction between the water and cement. An additional binding phase occurs from the extra pozzolanic characters. Secondly, the tricalcium aluminate (C₃A) in the cement reacts with the calcium carbonate (CaCO₃) in the MP to form calcium carboalumination. This combined increments both the cement compressive strength and hydration rate.

Rodrigues et al. (2015) stated that super-plasticizer additives are required to get the request cement properties, which is partially replaced by MP. In the lack of super-plasticizers, they reported negative effects on the concrete mechanical properties at substitute rates above 10%.

2.5 Workability Tests for Grouts

Marsh cone test is a common technic to evaluate the rheological properties of cement base grouts in field applications. The time it passes one liter of sample to flow through a Marsh cone. This test is defined as marsh cone flow time (MCFT) or marsh viscosity and the rheologic attitude of the grout can be predicted by using this time. But, specific viscosity or yield stress cannot be found by using this test. Lombardi (1985) invented a cohesion meter that can be used in conjunction with the Marsh viscosity to evaluate the apparent viscosity of the grout. With using cohesion and MCFT, apparent viscosity can be estimated by using the chart. The unit of

cohesion will be used as millimeters and the unit of MCFT will be taken as seconds and then viscosity value will be divided by unit weight. Finally, this value multiplied by the unit weight and converted centipoises (cP) to find the apparent viscosity. The results obtained from the chart and the results obtained from the rheometer test machine were compared to each other by Lombardi (1985), the results were seen close to each other.

The MCFT is a flowability test used for the properties and quality check of CBG and cement mortars which developed by Bartos et al. The volume of this device has 1500 ml and 5 mm inner cap. The MCFT is used to detect the CBG volume through flow cone at a measured time. The CBG mix was proud in a cone (1250 ml) and bottom outlet was turned on. After that, CBG mix begins to flow and elapsed time was measured providing that 1000 ml of CBG had flowed. Consequently, the elapsed of time gave the MCFT time. The MCFT time of water was found as 24 s in comparison with cement based grout.

The mini-slump test was used to find the spread of grout mixtures. The apparatus shape is same to the slump cone described by ASTM C-143 (Çelik et al., 2015). Dimensions of mini-slump apparatus; 38 mm high with at the top diameters of 57 mm and 19 mm at the bottom (Çelik et al., 2015; Kantro, 1980; Ozawa et al., 1995). In the mini slump test, CBG mix is poured into a cone until it's full. Then, the mixture is allowed to spread by removing the mini slump cone. It is transfer to on a flat glass plate. In the vertical direction the spread diameters are measured and the average spread diameter is calculated.

Lombardi plate cohesion meter (PCM) was used to find the cohesion. PCM consists of a steel plate with rough surfaces on both sides. $10 \times 10 \times 3$ mm is a dimension of the PCM. PCM apparatus was used for the calculate of cohesion. The plate was immersed in the CBG mixture. Due to cohesion, the CBG mixture sticks on the plate. After that, the cohesion measured from the control mix was compared with that measured from the CBG mixes. All tests were done two times by preparing a new mixture for control purposes.

2.6 Unconfined Compressive Strength (UCS) of Grouts with Waste Marble Powder (WMP) and Fly Ash (FA)

In order to decrease the use of cement in the construction works, researchers have began to study formation of blended cements pozzolanic agricultural by- products compositions such as WMP and FA that can be replaced with cement at different ratios. While hydration of cement is going on, calcium hydroxide, Ca(OH)_2 , will start to exist as one of hydration products. The corruption of concrete is directlyrelated with it. After any pozzolanic additive is mixed with cement, calcium-silicate-hydrate as the main cementing component will be produced because of chemical reaction between the pozzolanic material and Ca(OH)_2 . Howeveri because of the reaction between the pozzolanic material and Ca(OH)_2 , the amount of harfull Ca(OH)_2 decreases and this reaction increase the usefull C-S-H amount.

Research on the use of MP as partial modification of concrete has been the subject of interest is nowadays. According to Ramezanianpour, A.A. (2009) proved that additional cementing materials are economical and environmentally friendly alternatives to ordinary concrete blends. Researchers have recently carried out studies on the use of MP to replace a portion of the concrete as cement. The repetition of previous researches has been about the efficacy and applicability of MP as an effective substitute material.

Rai et al. studied M30 class of concrete by partially substituting cement with 5 different percentages by weight of MP (0–20%) and found that compressive strength increments by 5–10% for below 15% substitute.

Vardhan et al. analysis of the cement mortar mixture, it reported improved workability in the case of partial substitution with 0-50% by weight of MP. The reported results show that 10% MP addition has been achieved to the maximum benefit of improved fluidity. In addition, the compressive strength for the cure of 28 days increased slightly until 10% change; after that, the strength decreases to increment with the substitution percentage. Replacement of cement in various rates by natural puzzolana and MP to prepare SCC was investigated by Belaidi et al. The experimental research illustrated developed rheological characters of concrete mortar by substitution of MP (10– 40%) but illustrated decreased compressive strength with the substitution of natural puzzolana and MP.

Aliabdo, A.A., et al., Arshad, A., et al., Hebhoub, H., et al. and Ergün, A. investigated a reduce in values of slump on incrementing the substitution cement percent by MP which was ascribed to the high amount of fines in MP. Small particles increment the demand for water in concrete. Arshad, A. et al. and Hebhoub, H. et al. had similar studies.

Aliabdo, A.A. et al. investigated the impact of partly substituting cement by MP for 2 w/b rates 0.40 and 0.50. Increase in UCS for up to 7.5% substitution for water binder rate 0.5 and small increment in UCS for up to 10% substitution for water binder rate 0.40 was shown.

Shirulea, P.A. et al. reported an appropriate percentage change of 15% replacement which illustrated an increment in compressive strength as compared to the control mix. The reduce in the quantity of tri-calcium silicate (C_3S) and di-calcium silicate (C_2S) for the fall in strength were stated as the primary contributors.

Ali and Hashmi noticed an increment in split tensile strength on partly substituting cement by MP by 10%. Ergun, A. achieved same results, but with increasingly lower values for higher substitution rates. It was also found that the flexural strength was improved by Ali and Hashmi by replacing the 10% cement by MP, it increased 10.73%. Also, Belaidi et al. found a reduction in the flexural strength of ordinary concrete. Soliman, N.M. found a rise in modulus of elasticity of concrete.

CHAPTER 3

OVERVIEW AND THEORETICAL BACKGROUND OF GROUTING

3.1 Principles of Grouting

3.1.1 Definition and purpose of grouting

The grouting technique is often used to increase soil characteristics and to transfer loads to strong ground layers. Also, it is also used as base stoppers to prevent excess water movements below the level of the excavation and to form a permeable curtain wall in order to ensure the stability of the slope, to prevent liquefaction.

3.1.2 Categories of grouting

Recently, there are 4 different grouting methods types in use; slurry (intrusion), compaction (displacement), jet (replacement), and chemical (permeation) grouting (Welsh, 1986). Figure 3.1 shows these grouting methods. Each one serves several aim and application for various equipment. Compaction and jet grouting are high-pressure applications, while slurry and chemical grouting are low-pressure methods. Jet grouting uses grouting pressure up to 69 Mpa and pressure in compaction grouting is about 2.7 Mpa.

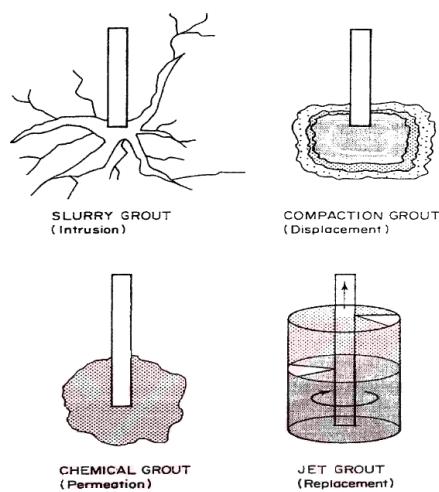

Figure 3. 1: Basic Models of Cement Base Grouting (Welsh.JP 1986)

3.1.2.1 Slurry grouting

The slurry grout fills the voids and cracks in the rock and ground passes the granular, coarse soils to create a cemented mass. Widespread uses; underlining the foundations, creating obstacles to groundwater flow, stabilize and strengthening of granular soils, providing excavation support.

The slurry grouting, also known as high mobility grouting or cement grouting, voids in rock/soil or fills pores in granular soil, with flowable particulate grouts. The grout void size and grain size must be suitably matched to allow the CBG to penetrate. According to the circumstances, microfine cement grout or portland cement is injected under pressure through strategic locations through multiple port or single port pipes. The grouted mass reduced permeability and incremented strength, stiffness.

The slurry grouting may provide an economic benefit for underpinning applications over alternative approaches like piling or replacement and removal and can be performed where reach is hard and area is limited. Since the effect of CBG is structural connections independent, this technique can be readily adapted to present foundations and can typically be successful without disrupting normal plant operations.

3.1.2.2 Compaction grouting

The compaction grout (CoG) concentrates the loose-grained soils, strengthens the stabilizes and fine-grained soils the underground sinkholes or voids by the staged injection of low mobility, low-slump aggregate grout. When treating the soil, an injection pipe is typically placed at the maximum processing depth. The grout is then injected as while the pipe is slowly raised in lifts, creating a column of overlapping grout bulbs. The expansion of the low mobility grout bulbs changes the location of surrounding soils. CoG increments the density, friction angle, and hardness of the granular soils around it. The effectiveness of the improvement can be increased by sequencing the low mobility (compression) grouting filling from the first to the secondary. In all ground, high modulus grout column strengthens the treatment site.

CoG was found in the 1950s as a remedial measure for the adjustment of building settlement. In recent years, low mobility grouting technology has improved to use a

wide area of subsurface conditions for corrective and new structures. These include poorly placed fills, karst conditions, collapsible or loosened soils, liquefiable soils, and rubble fills. This method has also been utilized in preventing ground settlement while tunneling through soft ground. Grout mix consistency should be under control for successful applications. A low slump very stiff soil cement grout is injected to compact and displace the soil. Grouts with high water content would act same to slurry grout and fracture through the soil skeleton. In general, compaction grout consists of silty sand, fly ash or cement, water and additives (accelerators, fluidifiers). This technique was used in Bolton Hill subway of Baltimore project to prevent settlement (Baker et. al., 1983) and in densification of a liquefiable stratum in West Pinopolis Dam site in South Carolina.

3.1.2.3 Chemical grouting

Chemical grouting (ChG) converts granular grounds into sandstone-like masses by filling gaps with a low viscosity, non-particulate grout. Sands with low fines are most suitable for this technique. The ChG is injected below pressure through the ports. The grout passes through the ground and hardens to form a sandstone-like mass. The grouted soil has decreased permeability and incremented stiffness, strength.

ChG offers the benefits of being well attainable in areas where space and access are limited, and where no structural connection to the foundation being underpinned is required. The application of a ChG is to ensure both underpinnings of existing structures and excavation support adjacent to an excavation. Normally, normal plant work operations can be carried out without interruption.

ChG equipment is suitable for tunneling applications in urban environments, either to balance the soil around separations or separations or to reduce the placement of overlapping structures within the effect of tunnel alignment.

ChG is the injection of appropriately formulated chemicals into sandy soils. The soil fraction passing by No. 200 sieve must be less than 20%. The product obtained is generally a sandstone-like material with UCS above 4.1 MPa. ChG are often used for water control purposes due to their positive properties like good control of set time and low viscosity. ChG is usually an ingredient of sodium bicarbonate and sodium

aluminate. Sodium silicate and acrylates (AC-400) sodium silicate are mostly used as grout materials.

3.1.2.4 Jet Grouting

Jet Grouting (JG) uses high-speed fluid jets to build the cemented ground of changing geometries in the soil. General uses; ensure excavation support, underpin foundations, technical details, seal the bottom of planned excavations. JG compose in situ geometries of soilcrete (grouted soil), using a grouting monitor annexed to the end of a drill stem.

JG pursue is advanced to the maximum treatment depth. Then high-velocity jets (CB with optional water and air) are started from ports in the monitor. The jets erode and blend the construction site soil with grout as the drill stem and monitor is rotated and raised.

According as the soil types and application, one of 3 types is used: the triple fluid system (water jet surrounded by an air jet, with a separate grout port), the double fluid system (slurry grout jet surrounded by an air jet) and the single fluid system (slurry grout jet). JG creates soilcrete panels, partial columns, or full columns with designed permeability or strength.

JG is efficient for the widest soil types variety of any grouting system, including most clays and silts. The physical and geometry characteristics of the soilcrete are designed based on the in-situ soils. As a system based on erosion, soil erosion plays an important role in predicting production, quality and, geometry. Cohesionless soils are typically more wear by JG than cohesive soils.

Jet grouting's capability to build soilcrete in limited areas and around subsurface obstacles like unique, provides, utilities design flexibility. In any case, which requires the groundwater control or requires the unstable soil excavation (water-carrying or otherwise) JG, it is generally a preferred solution.

Generally, JG may be performed without disrupting normal plant operations. The containerized development, highly mobile support equipment has decreased the costs and time of mobilization and demobilization. JG can usually result in saving the construction program time.

3.2 Properties Study on CBG in Porous Media

As the characteristics of the operation / handling procedures of grout injection and grout material are necessary for proving the effective practice of permeation grouting using CB, a correct comprehension of the grouting process and grout material parameters as explained in the following parts are incorporated in the existing study.

3.2.1 Grout material parameters

The particulate grouts permeability in the porous area depends on the various factors.

- Pressure filtration
- Stability
- Grain size distribution
- Rheology (mainly yield stress and viscosity)

As present above, the solution grouts are evolutive Newtonian liquids throughout their period of practical injectability, when penetration occurs in accordance with Darcy's law. Therefore, the main controls on grout properties and penetration distance,

Ground porosity and permeability.

First grout viscosity and evolution.

Deere (1982) stated that cohesion defines the travel distance and states the viscosity flow rate.

- Pressure (relate to flow time)
- Injection practical process

3.2.2 Grouting method parameters

The structure of the French Tunnel Union (AFTES 1991) offers a logical approach that defines the four (4) main parameters:

- Grout volume,

- Injection pressure,

- Injection rate,

- Time of injection,

3.3 Rheology of CBG

The rheological characters of CBG is considered complex (Håkansson, 1993). The grout consists of yield stress and thixotropic and non-Newtonian. In addition, cement hydration also plays an important role as rheological characters change over time. CBG rheology is a very important factor in the pumping, transportation, spreading and pouring of the material. In reality, CBG with w/c rates of 0.6-1.5, consisting of a solid volume concentration of about 30%-50%, are used (Rosqueo et al., 2003). In concrete, the shear rate increments with total ingredients and a complete breakdown can be accomplished at the end of the mixture. On the other hand, because of the lack of aggregates for the CBG, the surface space of the finer cement grain is higher and the rheology is more complex as a conclusion of the interaction between the suspended grains and the disintegration on shearing. Typical rates of the rheological characters of the cementitious substances are epitomized by Banfill (2003) and are illustrated in Table 3.1.

CBG and cementitious materials are subject to hydration, and the rheological characters vary accordingly. As noticed by Håkansson (1993) and abridged by Banfill (2006) and Sant et al. (2008), hydration proceeds in various phases. The first phase involves a fast effect between the anhydrous water and minerals, which leads to the peak of wetting. It then follows an accelerated phase, which is responsible for locking a slow reaction for two or more hours known as the sleep period. Ultimately, the fourth phase involves the retardation process. As a result, the apparent viscosity of the cementitious materials will change according to the hydration process.

The cementitious materials rheological characters are frequently expressed by a curve fitting a constitutive model to the shear rate vs. shear stress value. Various rheological characteristics are illustrated in Figure 3.2 Newtonian fluids do not have a yield stress and have a constant viscosity.

Pseudoplastic fluids do not have a yield stress but show a shear thinning character with increasing shear rate and can be shown using a power law model. Bingham fluids have a yield stress and stable viscosity. The yield pseudo plastic fluids have a yield stress and illustrate a shear thinning attitude with an incremented shear rate.

Table 3. 1: Typical values of rheological characters of cementitious materials
(Banfill, 2003)

| Material | Cement paste, | | Flowing | Self-Compacting | |
|----------------------|----------------------|---------------|-----------------|------------------------|-----------------|
| | Grout | Mortar | Concrete | Concrete | Concrete |
| Yield stress | | | | | |
| N/m ² | 10-100 | 80-400 | 400 | 50-200 | 500-2000 |
| Plastic viscosity | | | | | |
| Pa.s | 0.01-1 | 1.0-3.0 | 20 | 20-100 | 50-100 |
| Structural breakdown | | | | | |
| Significant | Slight | None | None | None | None |

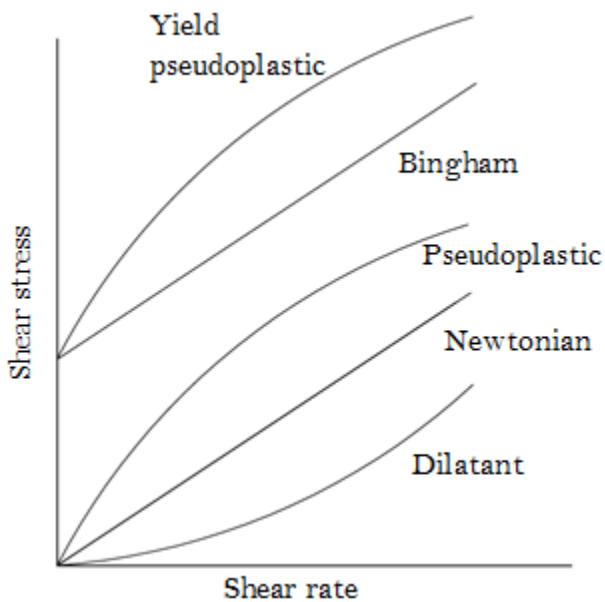

Figure 3. 2: Rheological characters of non-Newtonian fluids and Newtonian Yield pseudo plastic attitude can be shown by using the Modified Bingham model. Dilatant fluids exhibit a shear thickening attitude in which the shear rate increases. The Bingham model is generally used because of its simplicity and the linear relationship between shear rate and shear stress. However, the dense cementitious materials rheological attitude can be better illustrated with the Modified Bingham model because it can model the observed shear thinning attitude (De Larrard et al.,

1998). The Bingham model (Eq. 3.1) and the Modified Bingham model (Eq. 3.2) are illustrated as:

Bingham model ($\tau = \tau_0 + \mu_p \dot{\gamma}$)

(3.1)

Modified Bingham model ($\tau = \tau_0 + \mu_p \dot{\gamma} + c \dot{\gamma}^2$)

(3.2)

where τ = shear stress (Pa), τ_0 = yield stress (Pa), μ_p = plastic viscosity (Pa s), $\dot{\gamma}$ = shear rate (s^{-1}) and c = constant. As can be observed, both models contain yield stress. In the Bingham model, the viscosity is uttered in a linear relation with the shear rate in the Modified Bingham model. It shows resistance to the viscosity of the material flow and is defined as the relationship between the shear rate and the stress applied to the material. A change in the apparent viscosity could be found with changes of temperature.

3.3.1 Yield stress

Yield stress is the material property that expresses the transition between fluid-like and solid-like attitude. As a result, it is the minimum stress that allows the fluid to flow like an viscous material. Inter-particle forces between the solids in a suspension effect in yield stress that must be overcome to start the flow and applied stress that is lower than the yield stress will result in a deformation such as a solid instead of flowing. The presence of yield stress has been questioned by some authors, e.g. Barnes and Walters (1985), owing to the fact that dedicated direct measurements at very low shear rates, no yield stress obtained.

The concept of historical yield stress is summarized by Barnes (1999), and the argument on the presence of yield stress was finalized by the fact that it is acceptable to define the material attitude with yield stress over a limited shear rate range; on the other hand, this is shown by limited data.

The problem related to the yield stress is the complexity in deciding it. Theoretically, at the yield stress, the apparent viscosity of the material alters from a finite value to infinity; for this reason, an infinite test period is needed (Barnes 1997; Barnes 1999). Yield stress fluids exhibit an elastic attitude before attaining the yield stress. Before

reaching the yield stress, the material attitude alters to non-linearity from linearity and residual stress is monitored after the highest stress. For this reason, the definition of yield stress is also a matter of debate, and a series of yield stress may be used for practical applications (James et al. 1987; Mujumdar et al. 2002).

3.3.2 Viscosity

Viscosity (η) is the proportionality factor that links the shear resistance (τ) in the fluid to the slope velocity or the shear stress rate of the flow rate, which represents the rate at which a fluid layer moves relative to an adjacent layer (Newton's viscosity law). It is also named the absolute viscosity or apparent viscosity.

Viscosity is a significant fluid characteristic when analyzing fluid behavior and liquid motion near solid boundaries. The fluid viscosity is a measure of its reluctant to gradual deformation by shear stress or tensile stress. The slip resistance in a fluid is induced by intermolecular friction when the fluid layers try to slide from each other.

There are two relevant fluid viscosity measurements

- dynamic (or absolute)
- kinematic

3.3.2.1 Dynamic (absolute) viscosity

Absolute viscosity coefficient of absolute viscosity is a measure of internal resistance. The dynamic (absolute) viscosity is the tangent force per unit area needed to move a horizontal plane relative to the other plane in the unit velocity while maintaining a unit distance in the fluid.

The shear stress between the layers of a non-turbulent fluid moving in straight parallel lines can be identified as for a Newtonian fluid.

3.3.2.2 Kinematic viscosity

Kinematic viscosity - the absolute viscosity rate to density - a force-free amount. The kinematic viscosity can be got by dividing the liquid absolute viscosity by the liquid bulk density.

3.3.3 Measurement techniques

The rheological characters of CBG are measured in the field and the laboratory. The instruments used in the laboratory are not robust and the instruments used in the field are quite primitive and their results are not reliable and can be difficult to reproduce (Håkansson and Rahman, 2009).

3.3.3.1 Laboratory measurement

Laboratory measurements are done using various types of rotational and tube viscometers. Rheological characters can be measured by rotational viscometer using direct and indirect techniques. As stated by Nguyen and Boger (1983), indirect methods can be called extrapolation of the rheological shear rate-shear stress data, ie extrapolation of flow curves, assuming various rheological models. The direct methods are, for instance, the loosening the shear stress method and the shear vane method.

Concentric cylinder geometry is often used when measuring the rheological characters of CBG by using the rotational viscometer. This has the advantage that this geometry requires just a small sample that can be illustrated for a longer time period. Also, a measurement must be made with the concentric cylinder geometry, because the thinning phenomenon of the wall is inevitable when measuring a thinner thixotropic fluid (Barnes, 1995). Wall slippage occurs when the dispersion phase (concentrated suspension) slides away from the solid boundary and leaves a low viscous layer next to the smooth wall. Since CBG produce lots, a relatively large gap is required when using the concentric cylinder geometry, which paradoxically results in a greater sliding impact. Also, the wall surfaces can be roughening to reduce the slip.

For the elimination of the effect of wall slip, Nguyen and Boger (1983) introduced the vane technique. Various measurement geometries were used, e.g. the complexity and a concentric cylinder united with the measurement at the model fitted parameters and low shear rates were studied. The importance of measuring the shear stress-shear rate data by a direct method was emphasized. The measurement with the vane geometry is free of the vane dimension and size and has been demonstrate to be more correct for highly concentrated thixotropic suspensions. Another study by Nguyen

and Boger (1987) indicated that when the suspension of a concentrated thixotropic material was measured using a concentric cylinder, the sample could be cut partially due to the yield stress. Furthermore, the measured shear stress will also depend on the rotational speed of the bob that is applied. Besides the impact of the applied rotational speed, the measured shear rate will vary owing to the time-dependent attitude of the sample material.

Tube viscometers are the most widely used tools for measuring viscosity because of their simplicity and low cost. When a fluid is pressurized through a pipe, the velocity becomes the maximum at the center, indicating that the speed gradient or shear rate is zero at the maximum and center at the pipe wall. The wall shear stress is got from the pressure difference at a known distance. Shear rate, a Newtonian fluid and a correction factor; Apply Rabinowitsch - Mooney to determine the shear rate of a non-Newtonian fluid. Consequently, the wall shear stress and the wall shear rate curve are got, on condition that pipes of various diameters with the same L / R rate are used.

When pipe viscometers are used, the wall slip event is significant for CBG. A cement layer is depleted at the pipe wall, and the smooth surface provides a lower grout viscosity. Therefore, the wall cutting speed should be corrected due to slip. Further details of the tube viscometer can be found in Mannheimer (1991), Barnes (1999).

3.3.3.2 Field measurement

The rheological characters of CBG are usually measured in the field by basic tools, like a Marsh cone flow time (MCFT) and yield stick. The MCFT is used to find the fluidity of CBG in the field. In fact, this is a workability test to control the properties and control the character of CBG. The longer the time required for the grout to flow out of the cone, the lower the flowability. The the grout flow time may be related with the viscosity assuming a Bingham plastic material, provided that the grout density and yield stress is known. The yield stress can be found by the ‘raise pipe’. Here the grout is inserted into a vertical raising tube, and the principle is that the flow stops when the maximum shear stress in the tube wall is below the yield stress. The fluid density should be known for this experiment (Håkansson et al. 1992). Moreover, the yield stress can be found by the yield stick in the field (Axelsson and Gustafson, 2006). Waste marble powder and fly ash type grouting material and water

/ cement rates of 0.75- 1.5, CBG was tested. Compared to rotational rheometers, the yield bar provided slightly lower yield stress values. It has been finalized that the yield stick can be used as a robust technique to find the yield stress of the CBG in the field. Moreover, it can be combined with the MCFT to find the CBG viscosity. Referring to the yield stress as cohesion, a simple tool, called the plate cohesion meter (PCM), was presented by Lombardi (1985).

PCM apparatus was used for the calculate of cohesion. The plate was immersed in the CBG mixture. Due to cohesion, the CBG mixture sticks on the plate. While these techniques are used in the field, the results generally lack accuracy and reliability (Håkansson et al. 1992).

CHAPTER 4

AN INVESTIGATION OF FRESH AND HARDENED PROPERTIES OF CEMENTITIOUS GROUT MADE WITH USE OF WASTE MARBLE POWDER (WMP)

4.1 Introduction

Cement Based Grout (CBG) is a widely used method for many applications in the geotechnical area (Nonveiller, 1989). Some examples of CBG applications are suspension grouting, emulsion grouting, solution grouting, compaction grouting, permeation grouting, displacement grouting and replacement grouting (Stille and Gustafson, 2010; Yeon and Han, 1997; Baltazar et al., 2012; Çınar et al., 2017). The rheological and permeability properties of the CBG are straightly involved with the penetrability and pumpability in cracks and soil voids.

CBG is mixed of water, cement, and admixture. For CBG mix design, different range of water-cement (w/c) ratio could be used. Figure 4.1 illustrates the different usages of CBG with various w/c ratios.

For the applications of permeation grout, w/c ratio of CBG range between 0.5 and 1 (Danot and Derache, 2007). The w/c rate of injectable grout ranges from 1 to 2. Also, the grout should be similar to the liquid that can be injected into the rock and soil (Baltazar et al., 2012). As for consolidation and repair of masonry structures, w/c rates must be between 0.5 and 1.5 (Miltiadou, 1991).

Mineral and chemical admixtures are used to develop the characters of CBG as durability, penetrability, rheological and fresh properties. Adding mineral admixtures to the CBG at different amount modify the rheological and fresh properties of injections. For various types of grout applications, various additions (Cement kiln dust, rice husk ash, FA, silica fume, metakaolin and bentonite) have been applied. (Ruggiero, 1984; Weaver , 1990).

Some recent studies showed that additive, like rice husk ash, have increased the durability, long-term performance and workability of CBG mix

(Sonebi et. al., 2013). Also, Singh et al. (2019) studied the utilization of Portland cement with WMP in concrete. They stated that the binary composition of the binders ensures environmental and economic benefits by decreasing the production of Portland cement (PC) and so CO₂ emissions. Consequently, the additives using in CBG applications reduce the cost of application but increment the flowability and the strength.

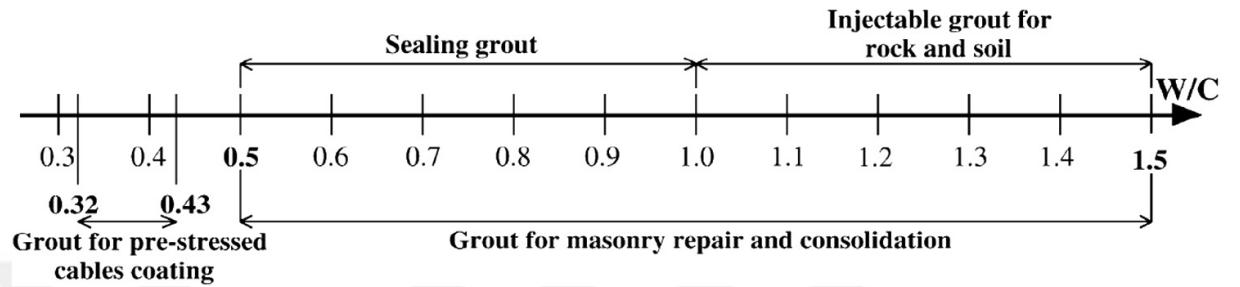

Figure 4. 1: Summary scheme of the various application areas of use of CBG
(Rosquoe et al. 2003).

Marble is a very important material for construction, particularly for decoration reasons. %25 percent of marble turns to powder and dust due to shaping, polishing, and sawing. The wastes of the marble factory have turned into a main environmental issue onwards the early of the 1990s. This problem is not only a local issue but also direct anxiety for all at of countries. In many countries, like Turkey, Italy, Iran, India, China, Brazil, Spain, Portugal, South Africa, USA, Pakistan, Finland, and Egypt, export the marble products, many other countries, like Germany, Japan, South Korea, and Taiwan, import them.(Alyamac et al., 2017). Turkey has forty percent of the world reserves of marble, and the storage of waste generated during production is of great significance. Turkey has approximately marble reserves of 3.872 million m³, of which close to $125 * 10^3$ t/year are produced in Afyon City. (Singh et al., 2019). Five thousand processing factories are used for marble production in Turkey. It is clear that these waste products reach millions of tons; so it is too difficult to store this quantity of wastes (Alyamac and Ince, 2009).

The disposal of Waste Marble Powder (WMP) is one of the most environmental concern all over the world nowadays. On the other hand, WMP can be used to increase the fresh and hardened properties of cementitious grout.

WMP is used like a complementary cement based material in the concrete (Pooja and Prof, 2014). Earlier researches concluded that maximum 10-15 percent of WMP can be conveniently mixed into the concrete without negatively impacting the durability, hardness and strength of the resulting concrete (Shirule et al., 2012; Aliabdo et al., 2014; Rodrigues et al., 2015). Another researches investigated the usage of WMP as a cement substitution and showed that combining of WMP in SCC with concrete reduce the splitting tensile strength, compressive strength, bulk weight, slump flow, ultrasonic pulse velocity, porosity and cost (Shirule et al., 2012; Aliabdo et al., 2014; Rodrigues et al., 2015; Yao et al., 2015; Uysal and Yilmaz, 2011; Gencel et al., 2012; Gesoglu et al., 2012; Alyousef et al., 2018).

Moreover, some investigators studied the flowing characteristic of paste and mortar to facilitate the SCC design process according to flow duration and flow spread (Shirule et al., 2012; Aliabdo et al., 2014; Rodrigues et al., 2015; Yao et al., 2015; Uysal and Yilmaz, 2011; Gencel et al., 2012; Gesoglu et al., 2012; Alyousef et al., 2018). Water/cement ratio used in all works were between 0.3 and 0.6. On the other hand, injectable grout is ranged from 1.0 to 1.5 in soil and rock (Çınar et al., 2017). Also, Water/cement can be used maximum 2.0 in jet grout application.

Most of the works cited in the literatures investigated effect of WMP on fresh and hardened characters of ordinary and SCC. The purpose of this study is to research the impact of high water-binder (w/b) rate and WMP content on the rheological characteristics properties and workability of CBG for geotechnical application such as improving strength, compressibility, and permeability. The studies were done on 24 CBG mixes including different amounts of WMP with the various percentages (5, 10, 15, 20 and 25%), of the total cement based materials weight and with 0.75, 1.00, 1.25 and 1.5 rates of w/c. A series of rheology and workability tests including Marsh cone flow time (MCFT) test, Lombardi Plate cohesion test, a coaxial rotating cylinder rheometer and mini-slump flow diameter test were conducted to observe the fresh characters of CBG mixtures. All study field experiments and modeling were not carried out.

4.2. Experimental Procedure

4.2.1. Materials used in this study

In this study portland cement (PC) (CEM I-42.5R) was used complying with ASTM C150 Type-I cement was used. WMP was used as an additive. Waste marble sludge (WMS) was provided in the form of a wet slurry from marble factory in Gaziantep-Turkey. WMS was dried in an oven at a temperature of 100 ± 10 °C for twentyfour hours and then sieved with 150 μm sieve (Fig. 4.2). Table 4.1 demonstrates the physical and chemical properties of PC and WMP.

Figure 4. 2: Waste Marble Powder

Table 4. 1: The physical and chemical properties of PC, WMP and FA

| Chemical composition(%) | Portland Cement(PC) | Waste Marble Powder (WMP) | Fly Ash(FA)* |
|--|---------------------|---------------------------|--------------|
| SiO ₂ | 20.27 | 3.86 | 62.35 |
| Al ₂ O ₃ | 5.32 | 4.62 | 21.14 |
| Fe ₂ O ₃ | 3.56 | 0.78 | 7.35 |

*(Cevik et al., 2018)

4.2.2. Mixture design

Water-binder (w/b) ratio is one of the important parameters that has a prominent impact on the fresh and hardened characteristics of CBG mix. So, in this experimental work four different (0.75, 1.00, 1.25 and 1.50) w/b rates were used to investigate the effect of WMP on the CBG. 24 injection mixtures with various WMP amount and various w/b rates were present to analyze the impact of WMP on the characteristics of CBG mixtures. (Table 4.2).

WMP was replace with cement substitutions of 5, 10, 15, 20, and 25% by volume. The control mix was prepared at each w/b rate. WMP wasn't added to the control mix. The mixture dosages, w/b ratio are shown in Tables 4.2.

Table 4. 2: WMP mix amount for 1.5 L and fresh and fluidity properties of the CBG mixtures.

| MIX ID | CEMENT (kg/m ³) | MP (kg/m ³) | WATER (kg/m ³) | W/b | MP (%) | Mini Slump (cm) | Marsh Cone (s) | Plate Cohesion (mm) |
|-----------|--------------------------------|----------------------------|-------------------------------|------|-----------|-----------------------|-------------------|---------------------------|

4.2.3 Mixing procedures

In preparation for the grout mixtures, five-liter laboratory mixer was used (Figure 4.3). The mixing procedure was applied in the experiment as following; WMP, cement and water were mixed at slow speed (120 rpm) for 1 min. The mixer was stopped and the paste remained on the sides of the bowl was scraped down. Also, grout mixtures were mixed by hand for 1 min. Eventually, the mixer was restarted at 240 rpm and the grout mixture mixed for 3 min.

Figure 4. 3: Laboratory mixer

Temperature and humidity of the laboratory for all tests were checked and measured as 50-60% and 20 ± 3 °C respectively. All CBG mixtures were obtained by using the same mixing procedures.

4.2.4. Test apparatus

4.2.4.1. Rheometer

Rotational viscometer (rheometer) was used to find the yield stress and the plastic viscosity (proRheo R180 Instrument, Germany) at 20 ± 3 °C. The viscosity of the grout can be measured at various rotational speeds. The rheometer determines viscosity according to the searle-principle; The proRheo R180 is a standard rotational model viscometer which uses a motor-driven bob turning in a fixed measuring tube (Figure 4.4). The specimen is sheared in the gap between the bob the tube and the

measured shear stress is used with the shear rate to compute the viscosity (Mezger, 2011).

Figure 4. 4: Rotational viscometer (Rheometer)

4.2.4.2. Mini-slump test, marsh cone flow test (MCFT) and plate cohesion test

The mini-slump test, MCFT and PCM test were used for evaluating the fluidity or workability of fresh grout mixtures. These tests were very easy to identify the flowability and workability characteristics of the grout prepared in the construction area.

The mini-slump test was used to find the spread of grout mixtures. The apparatus shape is same to the slump cone described by ASTM C-143 (Çelik et al., 2015). Dimensions of mini-slump apparatus; 38 mm high with at the top diameters of 57 mm and 19 mm at the bottom (Çelik et al., 2015; Kantro, 1980; Ozawa et al., 1995).

The MCFT is a flowability test used for the properties and quality check of CBG and cement mortars which developed by Bartos et al. The volume of this device has 1500 ml and 5 mm inner cap.

Lombardi PCM was used to find the cohesion. PCM consists of a steel plate with rough surfaces on both sides. 10×10×3mm is a dimension of the PCM.

4.2.5. Procedures

4.2.5.1. Rheometer

Ascending and descending flow curves in the shear stress–shear rate curve was obtained. The shear rates were varied between from 50 to 1000 s⁻¹ for every CBG

mixture. The apparent viscosity is regarded as a function of the shear rate; therefore, the shear-thickening (dilatant) attitude of the CBG mixtures is obtained with according to the apparent viscosity of GBG (Çelik et al., 2015).

To find the rheological properties of CBG, several types of analytical models exist. Plastic viscosity and yield stress are got by matching shear stress–shear rate curve values into Modified Bingham model. The modified Bingham model gives a preferable solution than the Bingham model for the same mixes (Khayat and Yahia, 1997). Figure 4.5 demonstrates the shear stress–shear rate curve values of MP5WB075 grout mixture by using both modified Bingham and Bingham model.

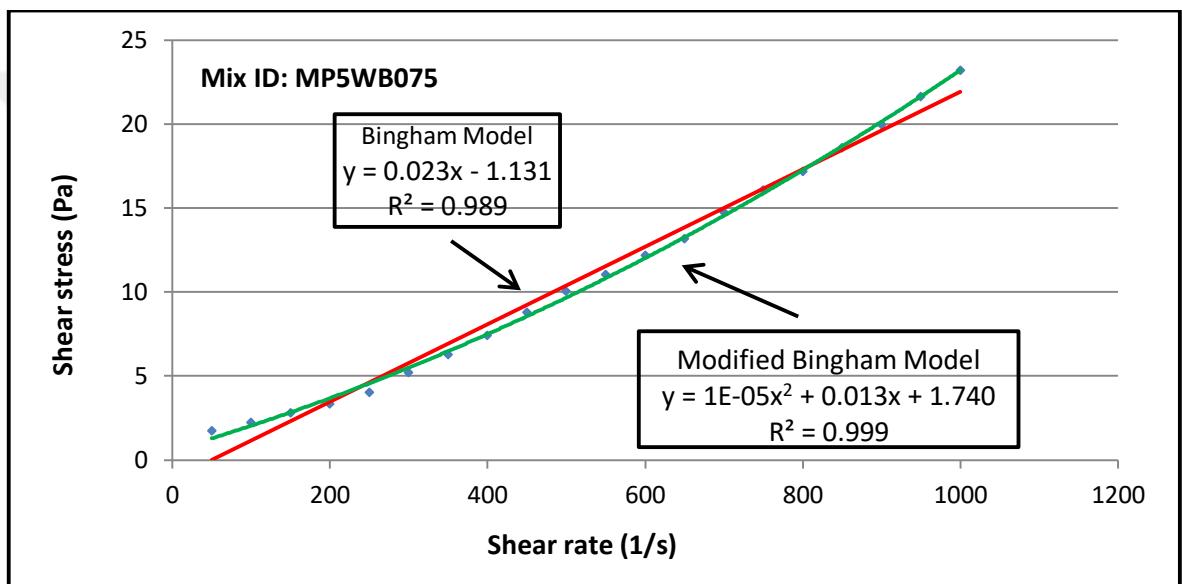

Figure 4. 5: The characteristic flow properties of CBG obtained from Modified Bingham and Bingham Model.

4.2.5.2. Mini-slump test, marsh cone flow test (MCFT) and plate cohesion test

In the mini slump test, CBG mix is poured into a cone until it's full. Then, the mixture is allowed to spread by removing the mini slump cone. It is transfer to on a flat glass plate. In the vertical direction the spread diameters are measured and the average spread diameter is calculated.

The MCFT is used to detect the CBG volume through flow cone at a measured time. The CBG mix was proud in a cone (1250 ml) and bottom outlet was turned on. After that, CBG mix begins to flow and elapsed time was measured providing that 1000

ml of CBG had flowed. Consequently, the elapsed of time gave the MCFT time. The MCFT time of water was found as 24 s in comparison with cement based grout.

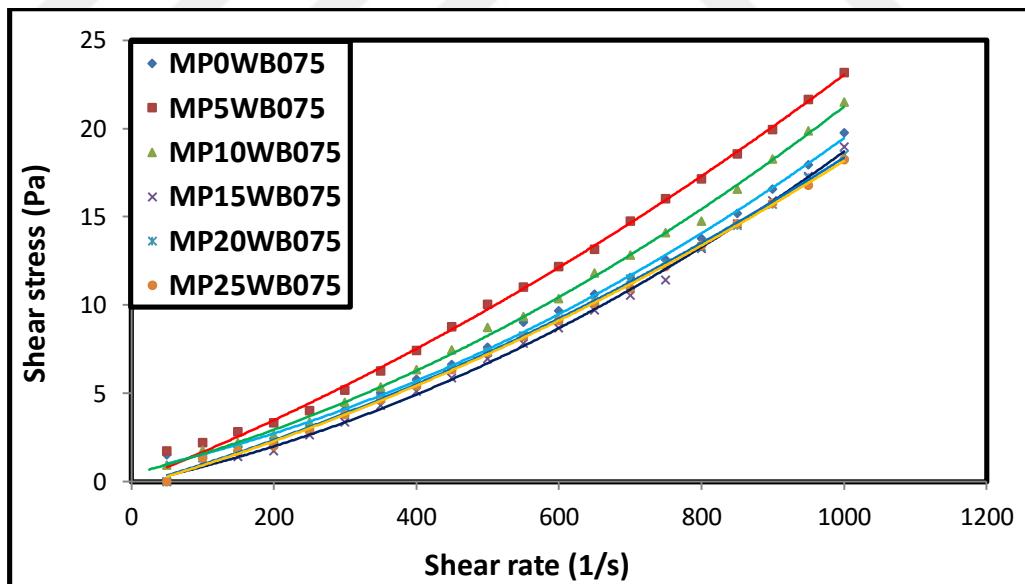

PCM apparatus was used for the calculate of cohesion. The plate was immersed in the CBG mixture. Due to cohesion, the CBG mixture sticks on the plate. After that, the cohesion measured from the control mix was compared with that measured from the other mixtures (Weaver and Bruce, 1991).

All tests were done two times by preparing a new mixture for control purposes. The test results were similar and were not indicated in the tables. All tests were made at 8-12 minutes after contact with cement and water.

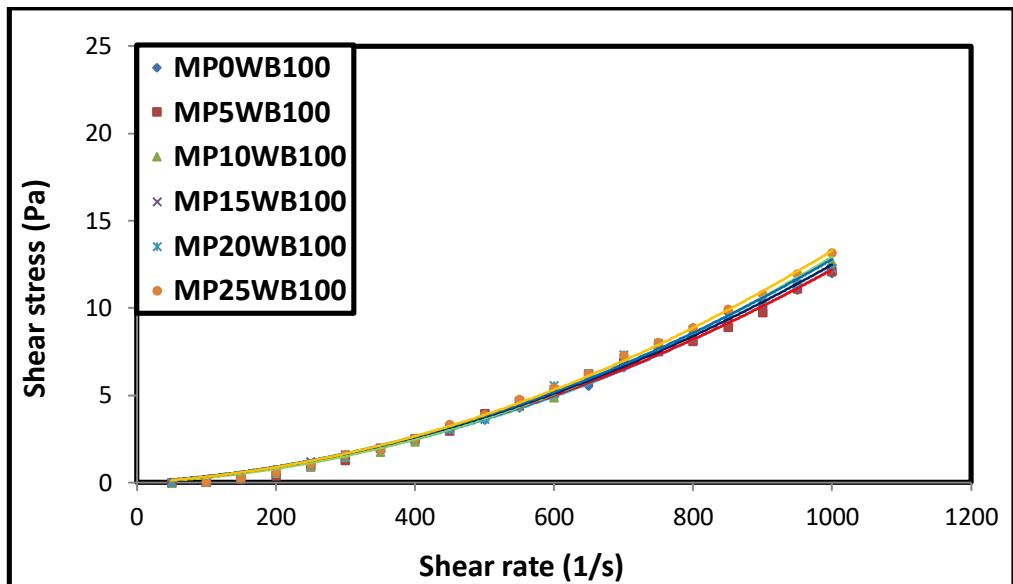

4.3. Results and Discussions

4.3.1. Rheological properties of CBG

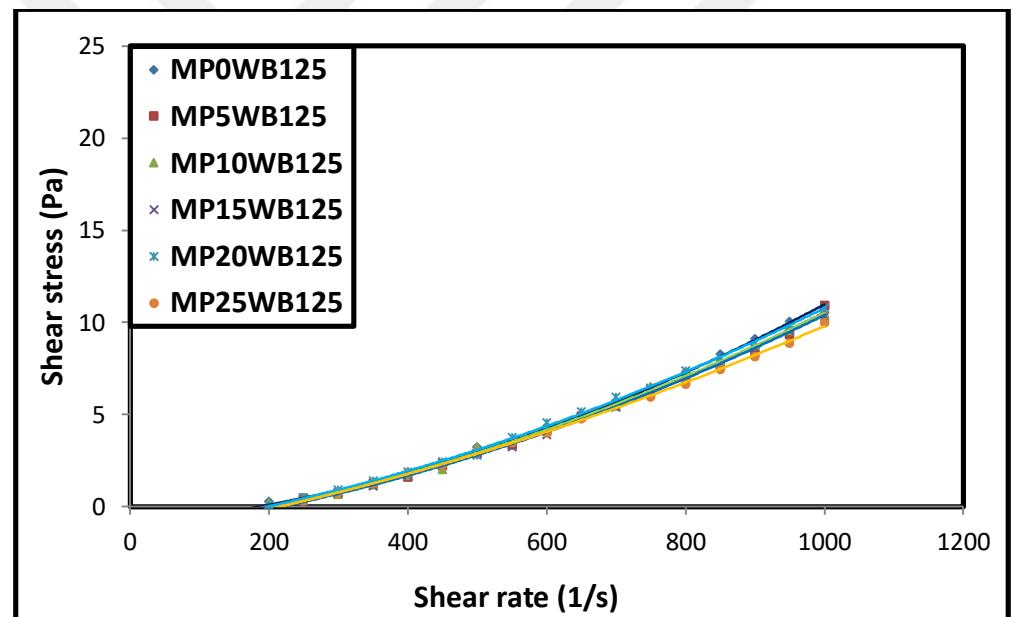

The influence of w/b rate and WMP content on the rheological properties of CBG mixture can be related with between the shear rate and the shear stress. The flow curves of the CBG mixes containing WMP with different w/b rates are illustrated in Figure 4.6.

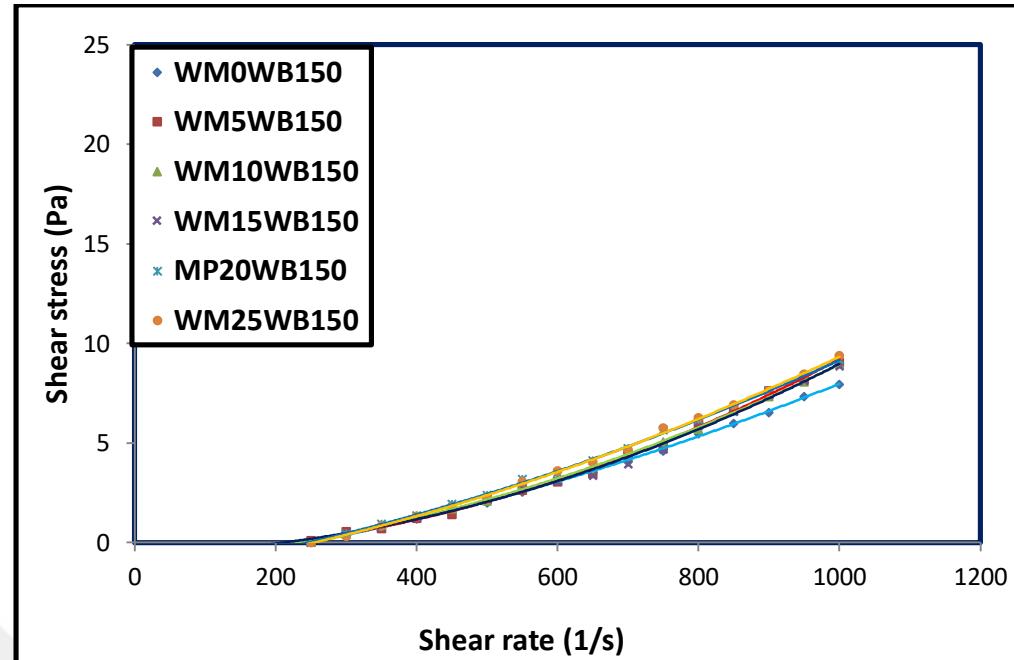

(a)

(b)

(c)

(d)

Figure 4. 6: Flow curves of CBG containing percentage of WMP between 5% to 25% with w/b rate of (a) 0.75; (b) 1.00; (c) 1.25; and (d) 1.5

The shear stress versus the shear rate curves were obtained by using modified Bingham model for grout mixtures. Table 4.3 shows the calculation of modified Bingham Model parameters. Authors used the values obtained from ascending and descending flow curves because it gives more accurate value. In Fig 4.6, the CBG mixtures illustrated shear-thickening attitude at all w/b ratios at all WMP content.

Figure 4.7 demonstrates how the plastic viscosity of different w / b ratios of CBG mixtures containing WMP is affected. It was observed that the increment in WMP amount in the CBG mixture increased the plastic viscosity with 0.75, 1.0, 1.25, 1.5 w/b ratios. Also, for the constant amount of WMP content, the increase in water-binder ratio reduces the plastic viscosity of the CBG mixtures. It can be concluded that the plastic viscosity of the CBG mix made at water-binder rate greater than 1.00 was directly impacted by the substitution of WMP.

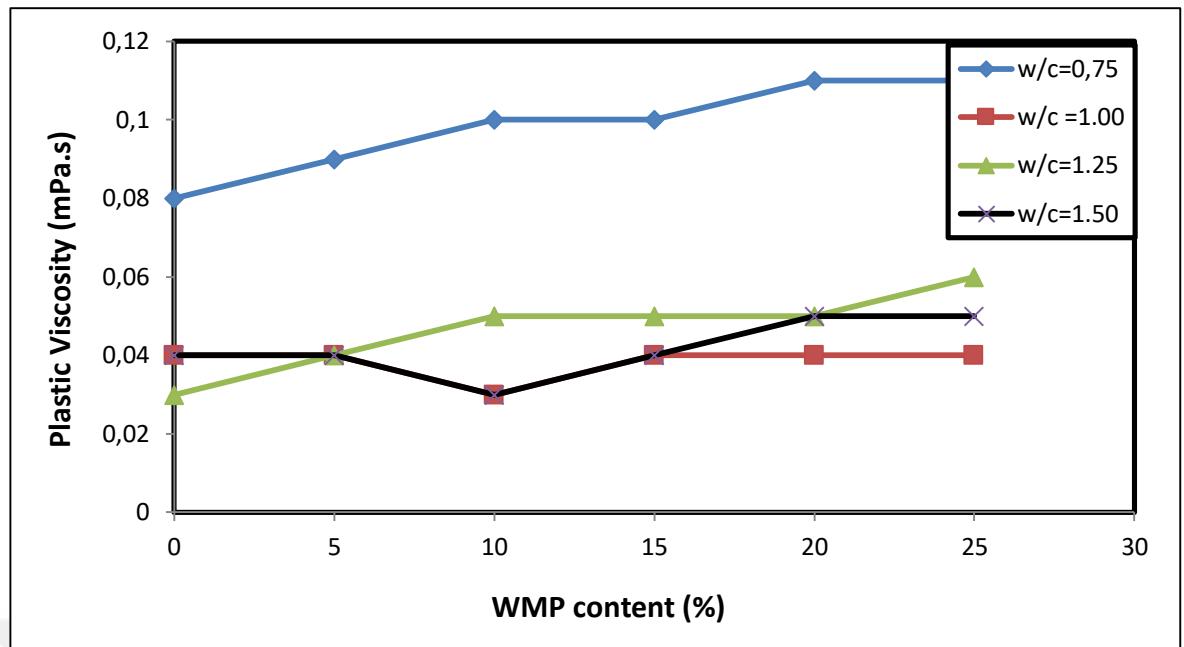

Figure 4. 7: Impact of WMP content at various water/binder rates on the plastic viscosity of CBG.

In table 4.3 and Figure 4.6, the apparent viscosity of the CBG mixture at shear rates from 50 to 1000 s⁻¹ for WMP addition at different water–binder ratios is listed. The increment in the apparent viscosity of the CBG mixtures showed that the dilatant response incremented with the increment in the percentage of WMP amount. It can be concluded that the high water holding capacity of WMP. All CBG mixtures have showed a shear-thickening attitude, as shear rate increase with the increase in apparent viscosity as shown in Fig. 4.6 and Table 4.

4.3.2. Fluidity properties of CBG

Fig. 4.8 a illustrates the relationship between WMP content and mini-slump flow diameter. It indicates that the increase in the percentage of WMP amount until %15 did not affect, but more than %15 WMP reduced the mini-slump flow diameter because of the angular particle shape of WMP (Gesoglu et al., 2012). Moreover, the increment in the w/b rate increment the mini slum flow for the constant WMP amount.

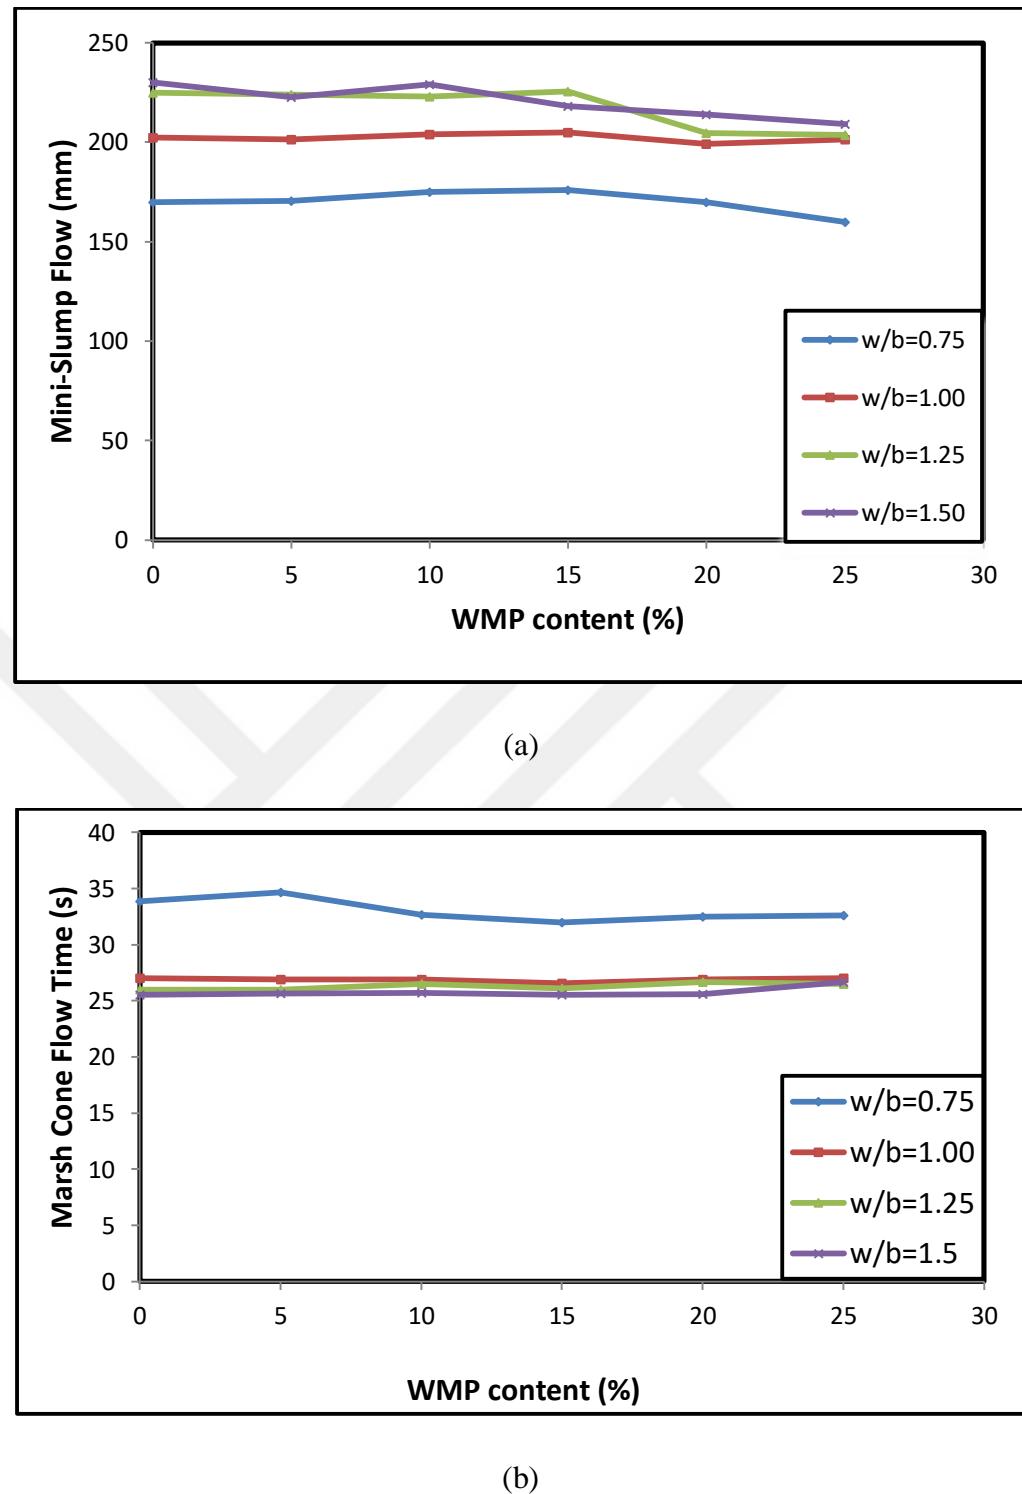

Figure 4.8: (a) Impact of WMP on mini-slump flow; (b) Impact of WMP on MCFT.

Fig 4.8b illustrates the impact of WMP amount on MCFT at various w/b ratios. It seems that the increase in WMP amount in the CBG mix, at all water-binder ratios, there is no effect on MCFT. Also, the increase in the w/b rate decrease the MCFT at the constant WMP content because of the water effect. Therefore, it can be

concluded that CBG mixtures with WMP reduce fluidity and workability characteristics when w/b is especially smaller than 1.00 in comparisons with w/b \geq 1.00. Similarly, the increase in WMP amount in the mix spectacularly decreases the deformability and fluidity of the CBG mixture at low water-binder ratios. The decrease in fluidity of grout mixtures, when WMP was added, can be interpreted that WMP has high capacity of water sorption. Similar results were reported by Aliabdo et al. (2014), Ashish (2018), Sing et al. (2017) and Ashish (2019).

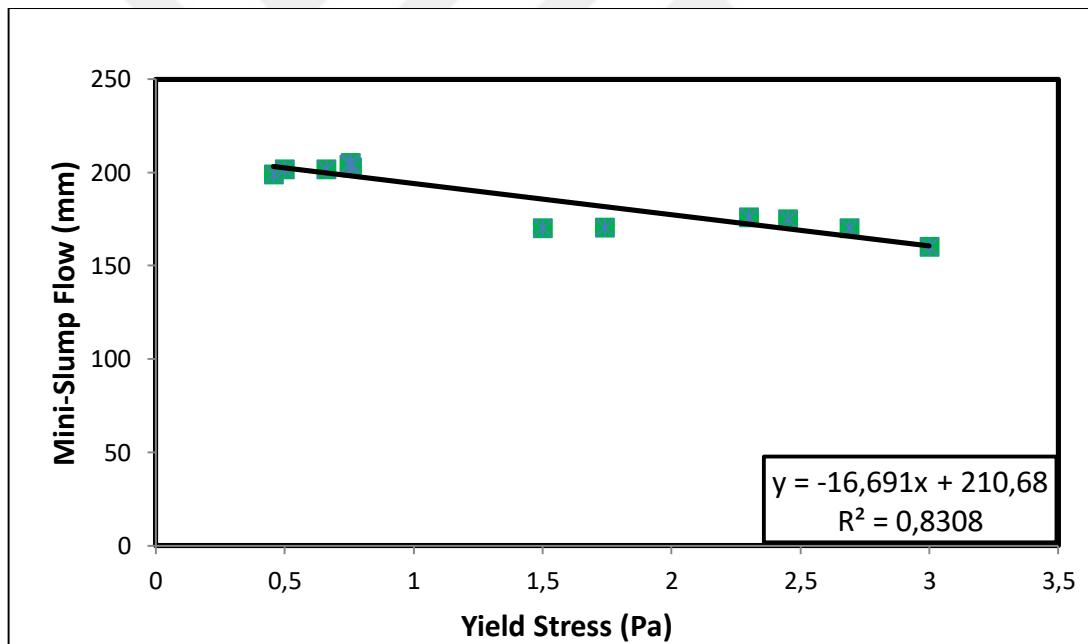

4.3.3.The comparisons between fluidity and rheological properties of CBG

The fluidity and the workability characteristics (MCFT, mini-slump flow and PCM) were correlated with two rheological values (yield stress and plastic viscosity) to providing easy and convenient methods for adjusting the rheological control of CBG mixtures. According to Zhang et.al (2016) and Ferraris et al. (2001), a fluid rheometer for cementitious paste is not properly existing in the construction industry for various causes. Like as the experiment device is fairly costly and the significance of using this kind of a device for cement paste was not defended up to lately. For this reason, the authors proposed easy tests like Marsh cone tests and mini-slump. In order to describe the relationship between rheological characters and workability of grout mixes, some graphs were drawn between test results of grout mixes and R^2 value between any of two grout mixtures were accounted. If correlation coefficient (R^2) values are above 0.80, then it can be considered that there is a good correlation between two test outcomes. If R^2 values are below 0.80, it indicates that there is a poor correlation.

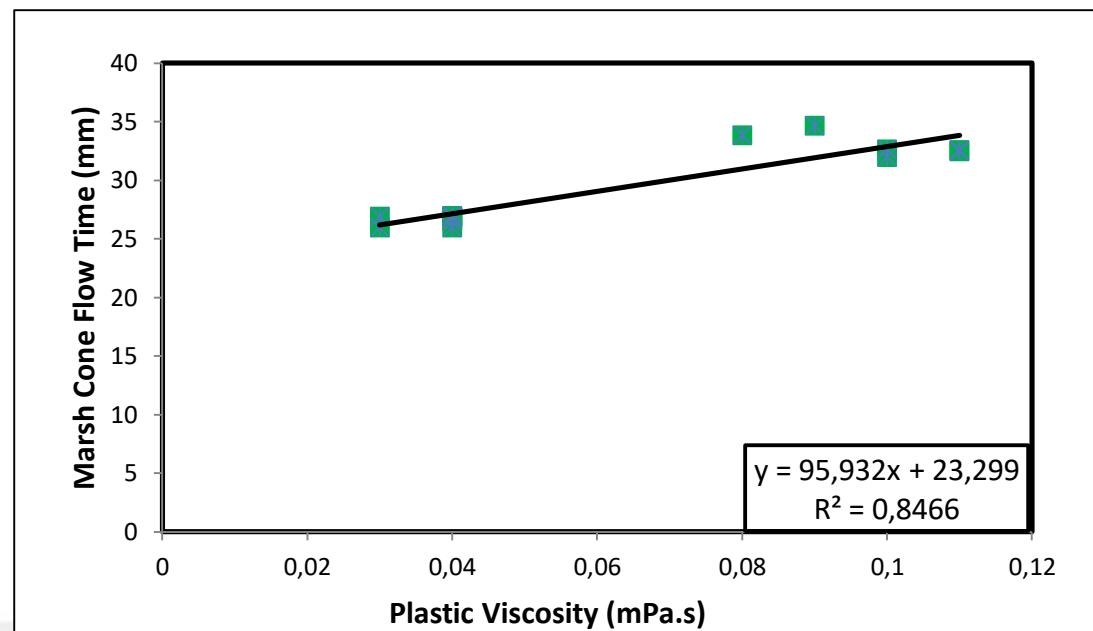

Fig. 4.9 displays the relationship between the rheological and the flowability characteristics, meantime Fig. 4.9a illustrates the relationship between the mini-slump flow and the yield stress. As it is known that the slump flow diameter gets some information's about the deformability of concrete which is associated with the yield stress (Ferraris et al., 2001). For this reason, there is a good correlation between mini-slump flow diameter of fresh mixes and the yield stress found from the modified Bingham model. From the graph, the relation between the yield stress and the mini-slump flow was a very good correlation ($R^2 = 0.83$). Furthermore, it seemed that the reduction in the yield stress incremented the mini-slump flow diameter. The results are compatible to the literature (Çınar et al., 2017; Çelik et al., 2015).

Figures 4.9b and 4.9c shown the relationship between plastic viscosity and MCFT and yield stress and Lombardi PCM test. Once the yield stress is exceeded, flowing of CBG mixture starts in the marsh cone test. In consequence of this reason, there is a direct relation between the MCFT measured and the viscosity. The marsh cone flow time test is a relatively simple test method to estimate the plastic viscosity value of grout mixture in the field applications (Ferraris et al., 2001; Sahmaran et al., 2008). Fig. 4.9b shown that the increment in plastic viscosity increased the MCFT of the CBG mix. In the figure 4.9b, it can be obtained that there is a good correlation ($R^2 = 0.84$). Therefore, a well defined demonstration of the plastic viscosity value could be estimated from the marsh cone flow time test.

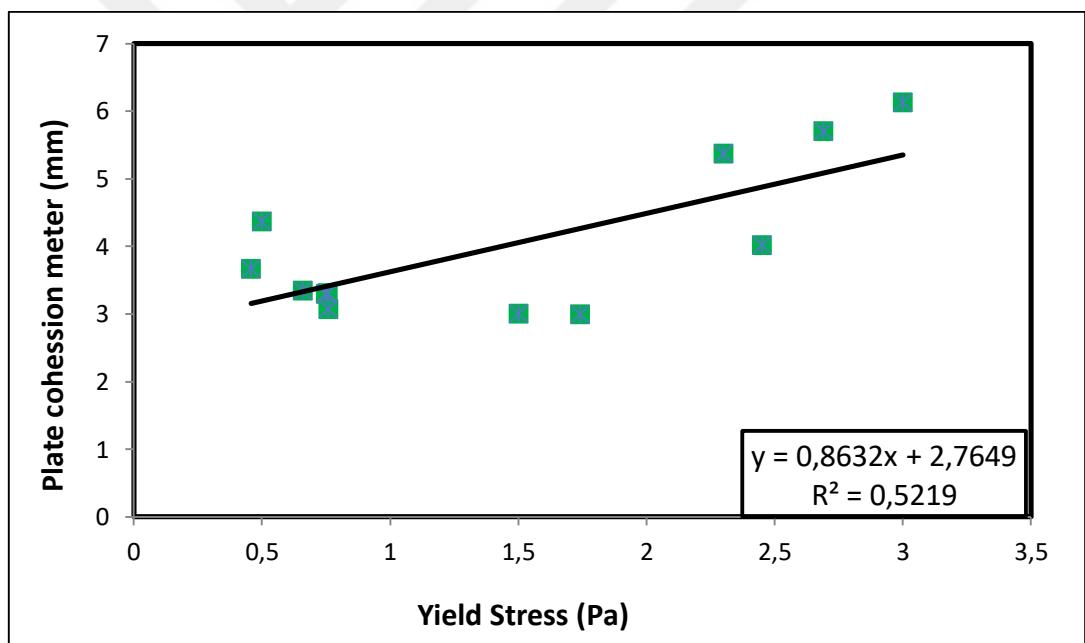

Also, It seemed that there is weak corelation between yield stress and Lombardi PCM test ($R^2 = 0.52$) (Fig 4.9c). The reason can be explained that other factors such as friction and shear rate may influence the cohesion of grouts.

Figure 4. 9: Correlation between workability and rheological characteristics of a mini-slump flow–yield stress, b MCFT–plastic viscosity and c PCM–yield stres

4.4.Conclusion

1. The rheological properties of the CBGs importantly have been improved by the addition of WMP to grout mix at various w/b ratios. Strongly shear thickening behavior was got from the CBG mixture the all w/b ratios and all WMP content.
2. The increment in the percentage of WMP in the CBG mixture incremented the plastic viscosity at all water–binder proportion. Moreover, the increment in water–binder rate reduced the viscosity of the grout for any given WMP content.
3. The increment in the percentage of WMP in the grout mixture reduced the mini-slump flow diameter. In a constant the percentage of WMP, the increment in water-binder rate incremented the mini-slump flow diameter because of the impact of water. Moreover, the MCFT reduced with an increment in w/b rate for a constant waste marble powder content. The workability and flowability of the CBG importantly changed with the increment in w/b rate in cement based grouts containing WMP.
4. The rheological characteristics (the plastic viscosity and the yield stress) of the CBG got from the modified Bingham model illustrates a good correlation with the MCFT and mini-slump flow of the grout ($R^2 = 0.83$, $R^2=0.84$). On the other hand, no correlation was found between yield stress and Lombardi PCM test.
5. According to fresh properties test results; Waste Marble Powder can be suitable for use in substitution cement in proportions up to 15%. For this reason, CO_2 emissions decreased by 15% and cost decreased by this rate.

CHAPTER 5

AN INVESTIGATION OF FRESH AND HARDENED PROPERTIES OF CEMENTITIOUS GROUT MADE WITH COMBINED USE OF WASTE MARBLE POWDER AND FLY ASH

5.1.Introduction

Cement Based Grout (CBG) is a widely used method for many applications in the geotechnical area (Nonveiller, 1989). Some examples of CBG applications are suspension grouting, emulsion grouting, solution grouting, compaction grouting, permeation grouting, displacement grouting and replacement grouting (Stille and Gustafson, 2010; Yeon and Han, 1997; Baltazar et al., 2012; Çınar et al., 2017). The rheological and permeability properties of the CBG are straightly involved with the penetrability and pumpability in cracks and soil voids.

CBG is mixed of water, cement, and admixture. For CBG mix design, different range of water-cement (w/c) ratio could be used. Figure 4.1 illustrates the different usages of CBG with various w/c ratios.

For the applications of permeation grout, w/c ratio of CBG range between 0.5 and 1 (Danot and Derache, 2007). The w/c rate of injectable grout ranges from 1 to 2. Also, the grout should be similar to the liquid that can be injected into the rock and soil (Baltazar et al., 2012). CBG mixes have usually water-cement ratios of 1.00 by volume.

Mineral and chemical admixtures are used to develop the characters of CBG as durability, permeability, rheological and fresh properties. Adding mineral admixtures to the CBG at different amount modify the rheological and fresh properties of injections. For various types of grout applications, various additions (Cement kiln dust, rice husk ash, FA, silica fume, metakaolin and bentonite) have been applied. (Ruggiero, 1984; Weaver, 1990).

Some recent studies showed that additive, like rice husk ash, have increased the durability, long-term performance and workability of CBG mix

(Sonebi et. al., 2013). Also, Singh et al.(2019) investigated the use of Portland cement with WMP in concrete. They stated that the binary composition of the binders ensures environmental and economic benefits by decreasing the production of Portland cement (PC) and so CO² emissions

Marble is a very important material for construction, particularly for decoration reasons. %25 percent of marble turns to powder and dust due to shaping, polishing, and sawing. The wastes of the marble factory have turned into a main environmental issue onwards the early of the 1990s. This problem is not only a local issue but also direct anxiety for all at of countries. In many countries, like Turkey, Italy, Iran, India, China, Brazil, Spain, Portugal, South Africa, USA, Pakistan, Finland, and Egypt, export the marble products, many other countries, like Germany, Japan, South Korea, and Taiwan, import them.(Alyamac et al., 2017). Turkey has forty percent of the world reserves of marble, and the storage of waste generated during production is of great significance. Turkey has approximately marble reserves of 3.872 million m³, of which close to 125 * 10³ t/year are produced in Afyon City. (Singh et al., 2019). Five thousand processing factories are used for marble production in Turkey. It is clear that these waste products reach millions of tons; so it is too difficult to store this amount of wastes (Alyamac and Ince, 2009).

FA is a divided siliceous tailing from the burning up of powdered coal and can be used an admixture. FA has the same fineness like PC. It can also react easily chemically with cement. Also, the average annual FA production in Turkey has about 13 million tons and half of it was utilized.

The disposal of WMP and FA are one of the most environmental concerns all over the world nowadays. On the other hand, WMP and FA can be used to increase the fresh properties of cementitious grout.

WMP is used like a complementary cement based material in the concrete (Pooja and Prof, 2014). Earlier researches concluded that maximum 10-15 percent of WMP can be conveniently mixed into the concrete without negatively impacting the durability, hardness and strength of the resulting concrete (Shirule et al., 2012; Aliabdo et al., 2014; Rodrigues et al., 2015). Another researches investigated the usage of WMP as a cement substitution and showed that combining of WMP in SCC with concrete reduce the splitting tensile strength, compressive strength, bulk weight, slump flow,

ultrasonic pulse velocity, porosity and cost (Shirule et al., 2012; Aliabdo et al., 2014; Rodrigues et al., 2015; Yao et al., 2015; Uysal and Yilmaz, 2011; Gencel et al., 2012; Gesoglu et al., 2012; Alyousef et al., 2018).

Usually, the percentage of FA usage is 10-35% in concrete (Yao et al., 2015). The usage of FA in concretes and SCC have also been investigated and have been well developed in the last decade (Uysal and Yilmaz, 2011). On the other hand, there is limited knowledge available concerning the fresh characteristics of cement based grout containing FA. The replacement of Portland Cement with FA is important for decreasing the viscosity, increasing passing ability and flowability of cement based grout materials (Gencel et al., 2012) .

The goal of this work is to illustrate the possible utilization of WMP and FA in preparing the grout mixture and to pursue the impacts of WMP and FA on the workability, fluidity, and rheological characters of CBG. The tests were made on 24 grout mixtures with the inclusion of different amounts of WMP+FA with the percentages of 10-30% + constant 25% (WMP+FA) of the total cement based materials weight and with 0.75 to 1.5 ratios of w/b. A series of rheology and workability tests with the inclusion of MCFT, Lombardi Plate cohesion test, a coaxial rotating cylinder rheometer, and mini-slump flow diameter test were conducted to pursue the fresh characters of CBG mix.

5.2.Materials and Methods

5.2.1. Materials

In this research Portland cement (CEM I-42.5R) was used complying with ASTM C150 Type-I cement. Class F FA was used an additive in CBG according to ASTM C 618. Also, WMP was used as an additive. Waste marble sludge (WMS) was provided in the form of a wet slurry from marble factory in Gaziantep-Turkey. The WMS was dried in an oven at 100 ± 10 °C for 24 hours and then sieved with 150 μm sieve Figure 5.1. Table 4.1 demonstrates the chemical and physical properties of PC, WMP and FA. Also, grain size distributions of PC, WMP and FA are shown in Figure 5.2.

Figure 5. 1: Waste marble powder, cement, fly ash

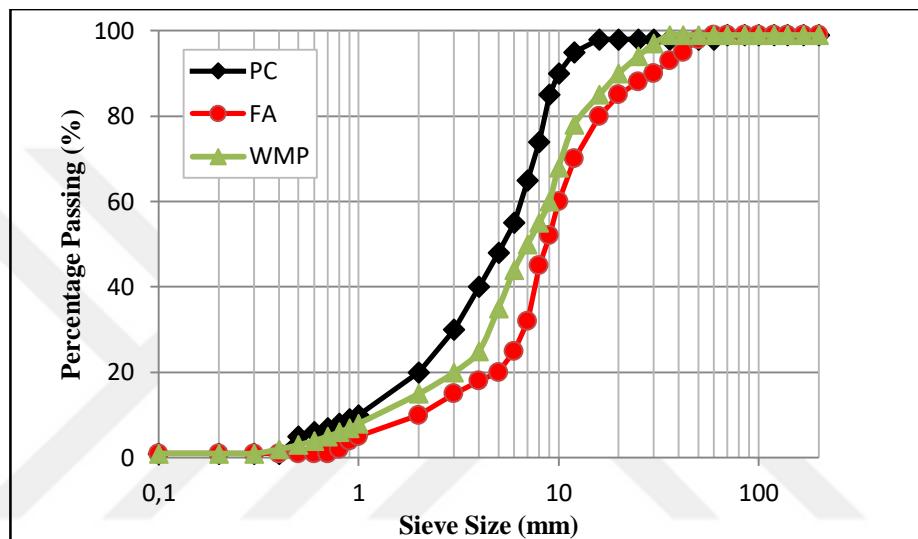

Figure 5. 2: Particle size distributions of PC, WMP and FA

5.2.2. Methods

Water-binder (w/b) rate is one of the significant factors that has a prominent impact on the fresh and hardened characteristics of CBG mixes. So, in this experimental work w/b 0.75, 1.00, 1.25 and 1.5 rates were chosen to research the effect of WMP+FA on the CBG. 24 injection mixtures with various WMP+FA amount were prepared to the impact of WMP, FA on the characteristics of CBG mixtures. (Table 4.1). WMP+FA was replace with cement substitutions of 10-30% + constant 25% by volume. The control mix was prepared with only PC and water at w/b 0.75, 1.00, 1.25, 1.50 rates. WMP and FA weren't added to the control mix. The mixture proportions are illustrated in Tables 5.1.

Table 5. 1: WMP+FA(constant) mix amount for 1.5 L and fresh and fluidity properties of the CBG mixtures.

| MIX ID | MIX NO | CEMENT (kg/m ³) | WMP (kg/m ³) | FA (kg/m ³) | WATER (kg/m ³) | w/b | FA(%) | WMP (%) | Mini Slump (cm) | Marsh Cone (s) | Plate Cohesion (mm) |

In preparation for the grout mixtures, five-liter laboratory mixer was used. The mixing step was applied in the experiment as following; WMP, FA, cement and water was mixed at slow speed (120 rpm) for 1 min. The mixer was paused and the remaining grout mixture on the sides of the container was stripped. Also, grout mixes was blended by hand for one minute. Lastly, the mixer was restarted at high speed (240 rpm) and the grout mixture mixed for three minutes. Temperature and humidity of the laboratory for all tests were checked and measured as 50-60% and 20±3 respectively. All CBG mixtures were obtained by using the same mixing procedures.

Rotational viscometer (rheometer) was used to find the yield stress and the plastic viscosity (proRheo R180 Instrument, Germany) at 20 ± 3 °C. The viscosity of the grout can be measured at various rotational speeds. The rheometer determines viscosity according to the searle-principle; The proRheo R180 is a standard rotational

model viscometer which uses a motor-driven bob turning in a fixed measuring tube. The specimen is sheared in the gap between the bob the tube and the measured shear stress is used with the shear rate to compute the viscosity (Mezger, 2011).

Ascending and descending flow curves in the shear stress–shear rate curve were gotten. The shear rates were varied between from 50 to 1000 s⁻¹ for every CBG mixture. The apparent viscosity is regarded as a function of the shear rate; for this reason, the shear-thickening (dilatant) behaviour of the CBG mixes is obtained with according to the apparent viscosity of GBG (Çelik et al., 2015).

To find the rheological properties of CBG, several types of analytical models exist. Plastic viscosity and yield stress are got by matching shear stress–shear rate curve values into Modified Bingham model (Eq. 3.2) τ_0 is yielding stress and μ_p is plastic viscosity. The modified Bingham model gives a preferable solution than the Bingham model (Eq. 3.1) for the same mixes (Çelik et al., 2015). Figure 5.3 demonstrates the shear stress–shear rate curve values of MP15FA25 grout mixture by using both modified Bingham and Bingham model.

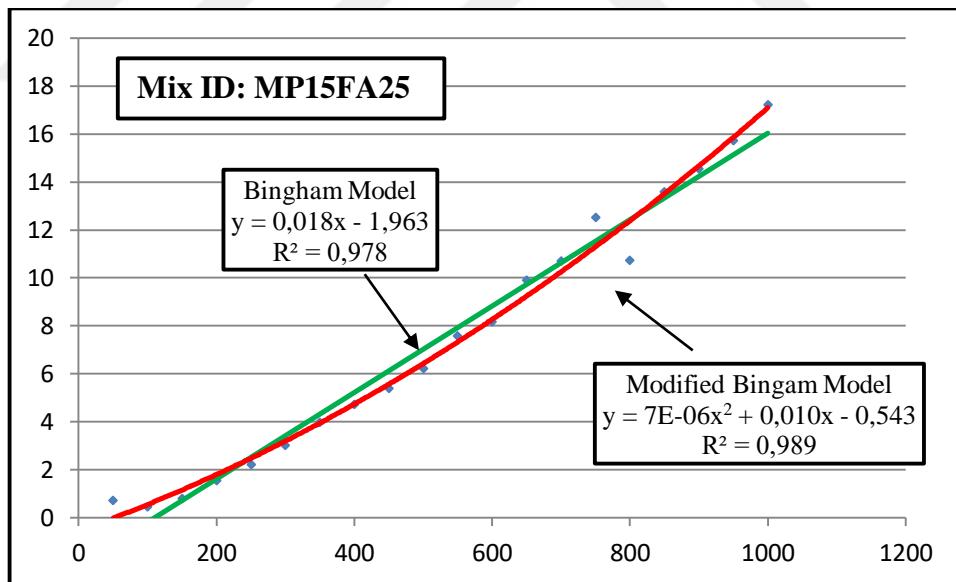

Figure 5. 3: The characteristic flow properties of CBG obtained from Modified Bingham and Bingham Model

The mini-slump test, MCFT and PCM test were used for evaluating the fluidity or workability of fresh grout mixtures. These tests were very easy to identify the

flowability and workability characteristics of the grout prepared in the construction site.

The mini-slump test was used to find the spread of grout mixtures. The apparatus shape is same to the slump cone described by ASTM C-143 (Çelik et al., 2015). Dimensions of mini-slump apparatus; 38 mm high with at the top diameters of 57 mm and 19 mm at the bottom (Figure 5.4) (Çelik et al., 2015; Kantro, 1980; Ozawa et al., 1995). In the mini slump test, CBG mix is poured into a cone until it's full. Then, the mixture is allowed to spread by removing the mini slump cone. It is transfer to on a flat glass plate. In the vertical direction the spread diameters are measured and the average spread diameter is found.

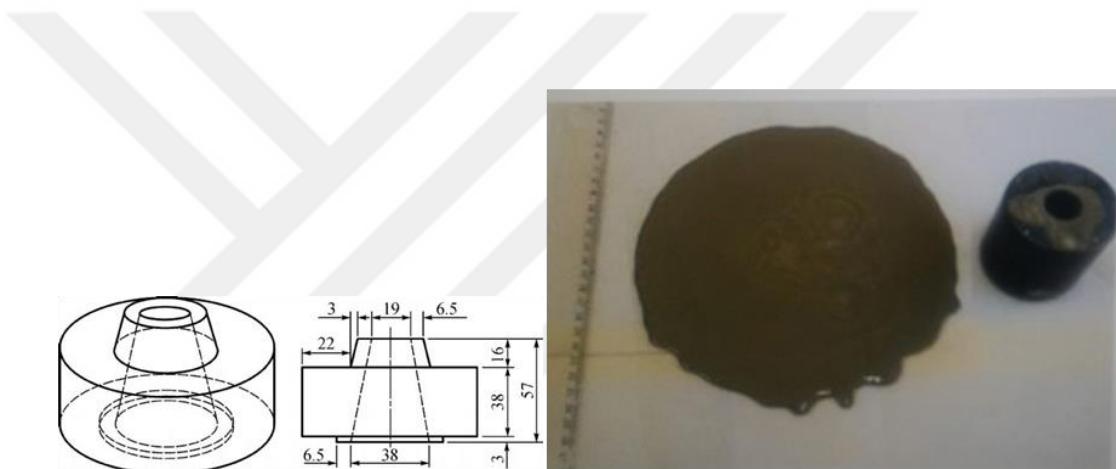

Figure 5. 4: Mini-slump test apparatus

The MCFT is a flowability test used for the properties and quality check of CBG and cement mortars which developed by Bartos et al. The volume of this device has 1500 ml and 5 mm inner cap (Figure 5.5). The MCFT is used to detect the CBG volume through flow cone at a measured time. The CBG mix was proud in a cone (1250 ml) and bottom outlet was turned on. After that, CBG mix begins to flow and elapsed time was measured providing that 1000 ml of CBG had flowed. Consequently, the elapsed of time gave the MCFT time. The MCFT time of water was found as 24 s in comparison with cement based grout.

Figure 5. 5: Marsh cone flow test apparatus

Lombardi PCM was used to find the cohesion. PCM consists of a steel plate with rough surfaces on both sides. $10 \times 10 \times 3$ mm is a dimension of the PCM (Figure 5.6). PCM apparatus was used for the calculate of cohesion. The plate was immersed in the CBG mixture. Due to cohesion, the CBG mixture sticks on the plate. After that, the cohesion measured from the control mix was compared with that measured from the CBG mixes. All tests were done two times by preparing a new mixture for control purposes. The test results were similar and were not indicated in the tables. All tests were made at 8-12 minutes after contact with cement and water.

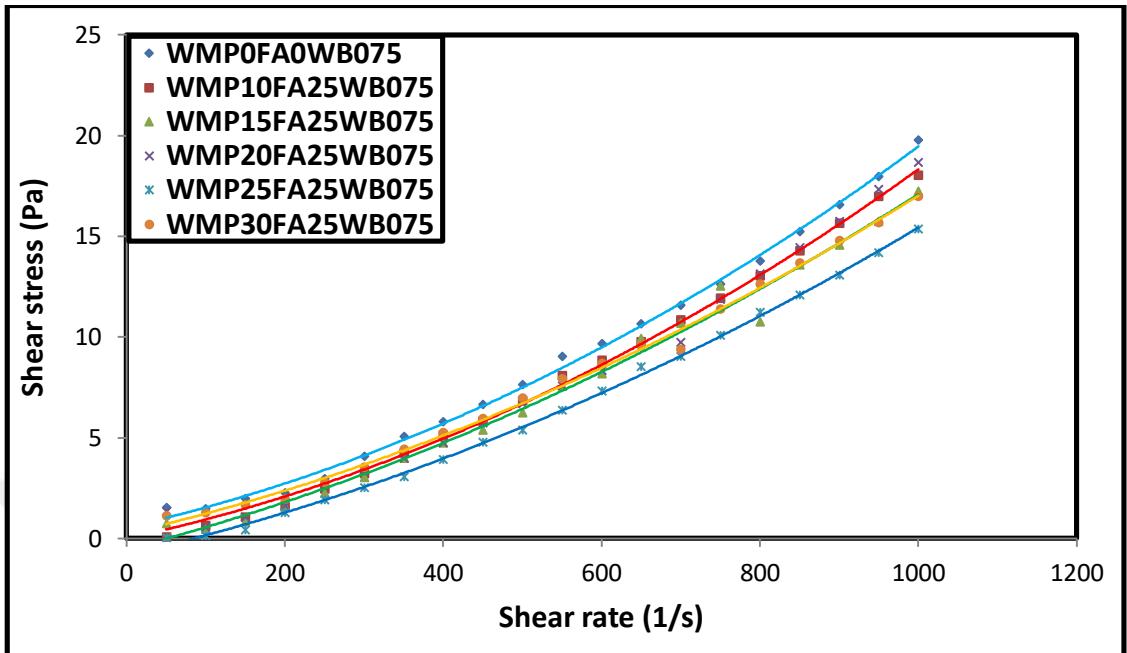

Figure 5. 6: Plate cohesion test apparatus

5.3. Results and Discussions

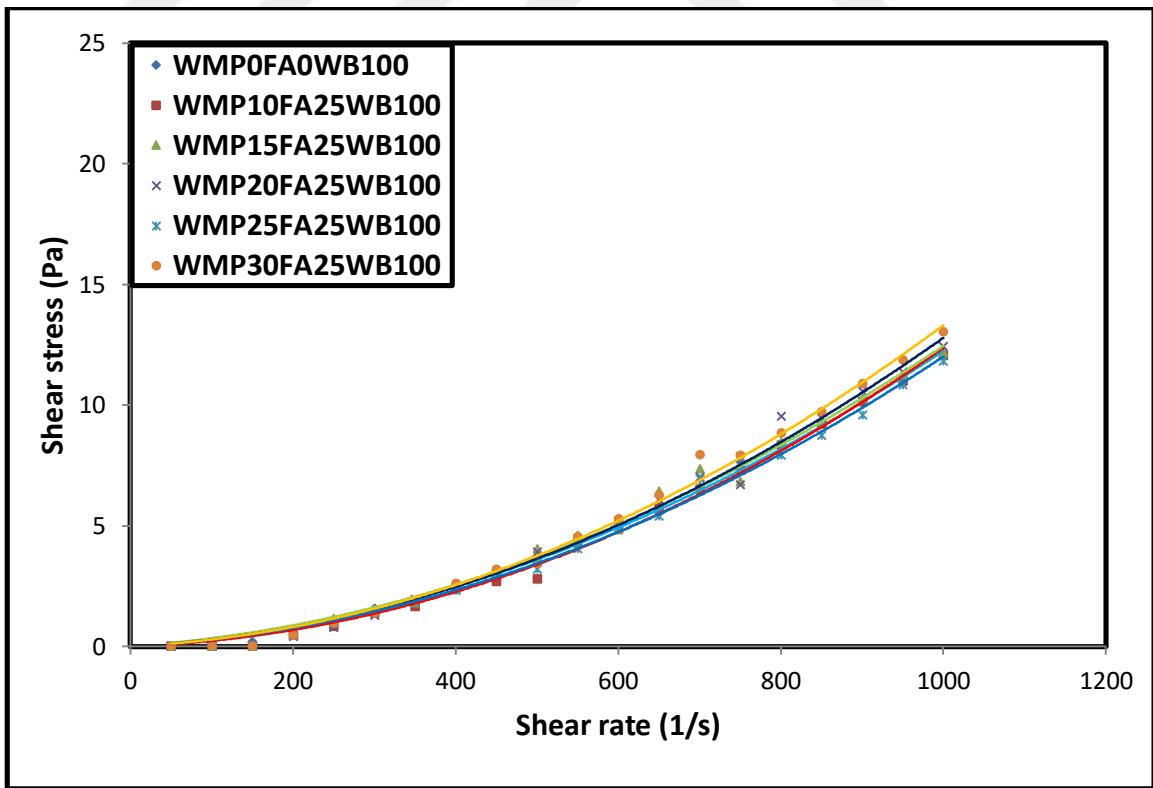

5.3.1.Rheological properties of CBG

The influence WMP and FA content on the rheological properties of CBG mixture can be related with between the shear rate and the shear stress. The flow curves of

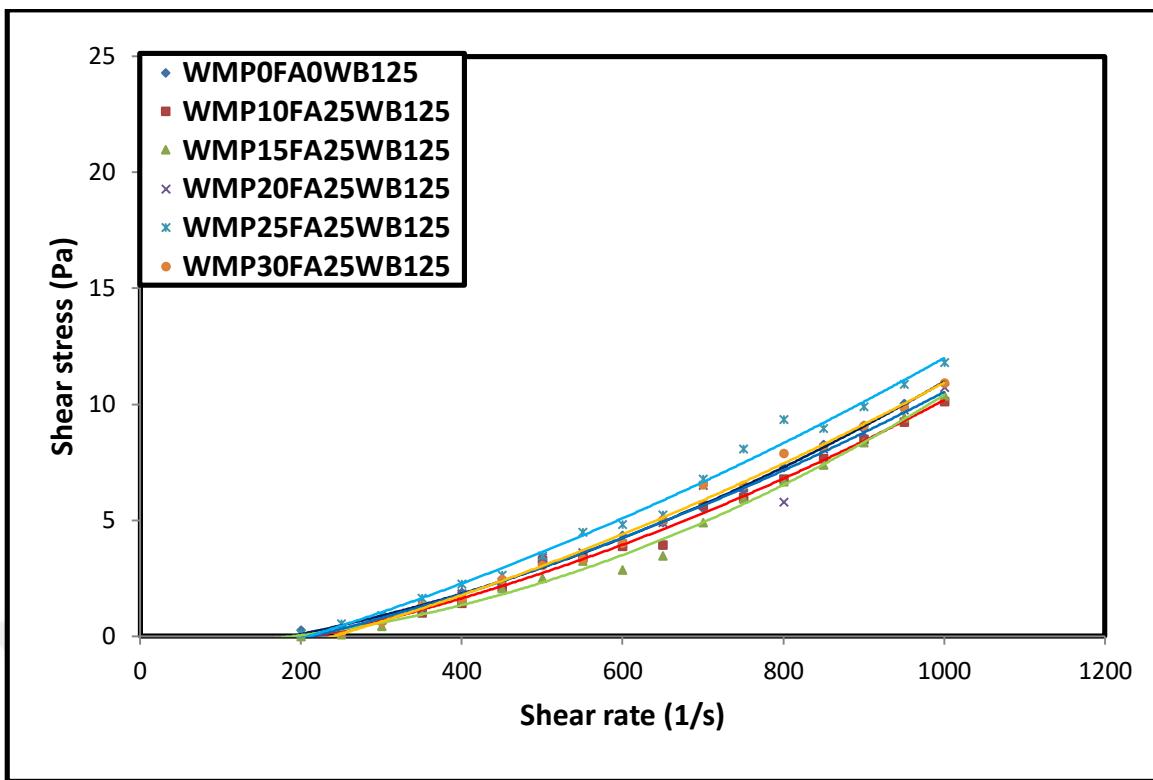

the CBG mixes containing WMP (w/b= 0.75, 1.00, 1.25, 1.5), FA (w/b= 1.00) and WMP+FA (w/b= 1.00) rate are shown in Figure 5.7.

 (a) 0.75; (b) 1.00; (c) 1.25; and (d) 1.5

The shear stress versus the shear rate curves were obtained by using modified Bingham model for CBG mixes. Table 5.2 shows the calculation of modified Bingam Model parameters. Authors used the values obtained from ascending and descending flow curves because it gives more accurate value. In Figure 5.7, the CBG mixtures illustrated shear-thickening attitude at all WMP+FA contents.

Table 5.2 demonstrate how the plastic viscosity (μ_p) of CBG mixtures containing WMP and FA are affected. It was observed that the increment in WMP amount in the

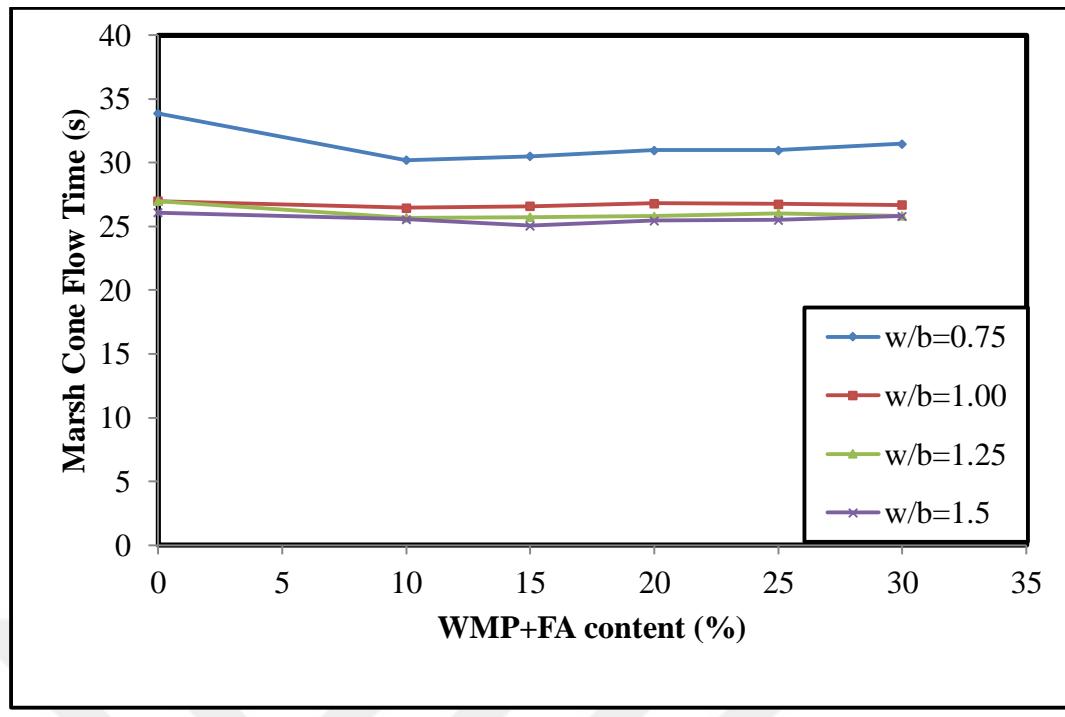

CBG mix increased the plastic viscosity in chapter 4. It can be concluded that the high water holding capacity. Similar result was reported by Singh et al. (2017). However, FA in the CBG mix decreased the plastic viscosity, owing to the spherical shape of the particles of FA (Jiménez et al., 2013; Cevik et al., 2018). Sha F. et al. (2018) found an decrease viscosity, this was primarily for the many amounts of SiO₂ and the “Ball Effects” of FA can evolve rheological characters of grout.

5.3.2. Fluidity properties of GBG

Figure 5.8(a) shows the mini-slump flow diameter of CBG prepared with the different amount of WMP+FA contents. It indicates that the increase in the percentage of WMP (10-25%) amount reduced the mini-slump flow diameter because of the angular particle shape of WMP (Gesoglu et al., 2012). According to the chapter 4 result, FA positively affected of the mini slump flow. The spherical shape of FA decreases frictional force between the angular particles of PC owing to the ball bearing effect.

(a)

(b)

Figure 5. 8: Effect of WMP and FA on mini-slump flow; (b) impact of WMP and FA on MCFT

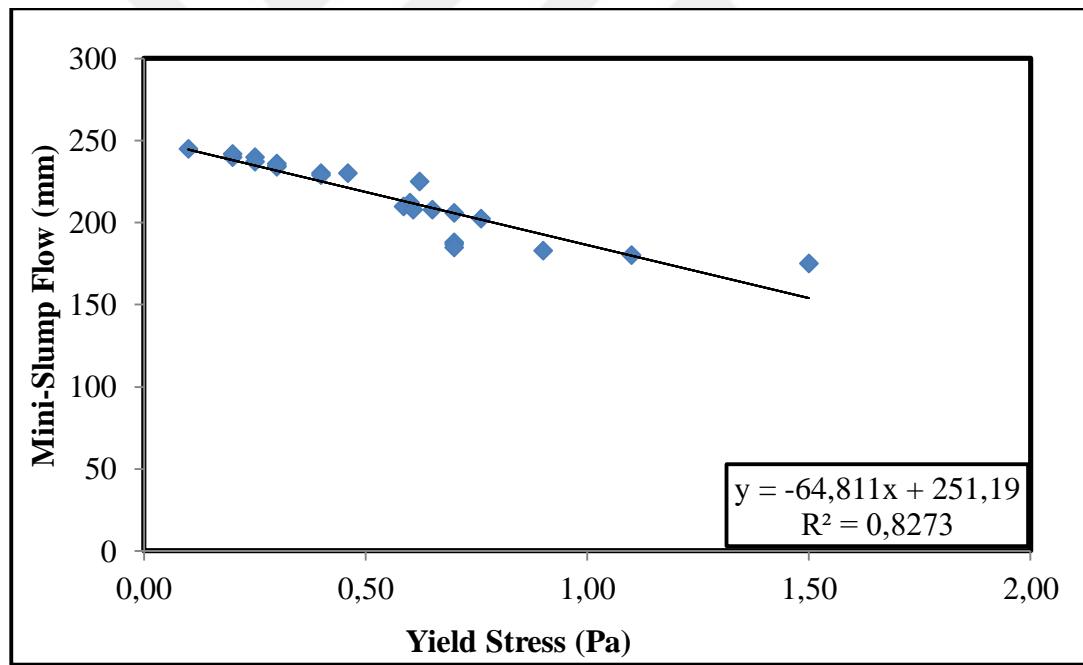

Figure 5.8(b) illustrates the impact of WMP and FA amount on MCFT at various w/b rate. It seems that the increase in WMP amount in the CBG mix, there is no effect on MCFT. Also, MCFT decreased with FA amount. It can be said that FA is able to improve the flowability of CBG. Same results were declared by Güllü, H. et al. (2019) and Sha. F. et al. (2018). Especially, FA increased the fluidity of CBG, while the WMP showed negative effect in increase the MCFT in WMP+FA content. Sing et al. (2017) found an decrease flowabilty on enhancement the substitute cement percent by WMP which was based on to the high fines percentage in WMP.

5.3.3. The Comparisons between fluidity and rheological properties of CBG

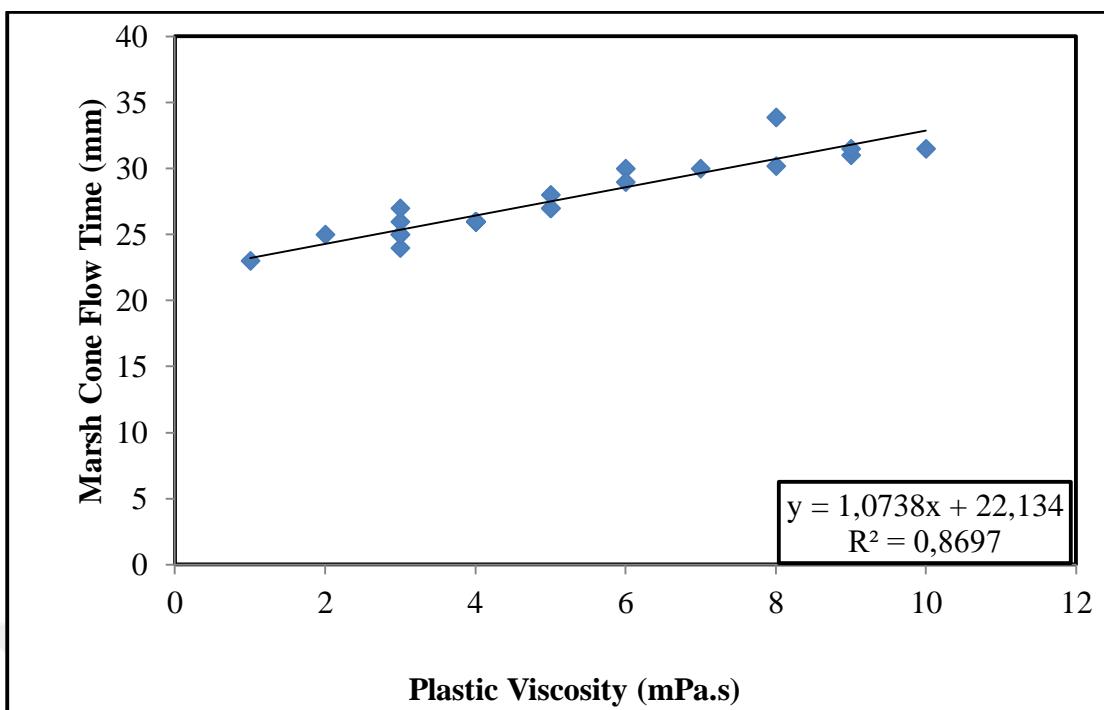

To descript the relation between two rheological values (plastic viscosity and yield stress) and the flowability and the workability properties (mini-slump flow, MCFT and PCM) of the CBG, the curves were drawn between the test outcomes and the R^2 value. If correlation coefficient (R^2) values are above 0.80, then it can be considered that there is a good correlation between two test outcomes. If R^2 values are below 0.80, it indicates that there is a poor correlation.

Figure 5.9 displays the relationship between the rheological and the flowability properties, meantime Figure 5.9(a) illustrates the relationship between the yield stress and the mini-slump flow. From the graph, the relation between the yield stress and the mini-slump flow was a very good correlation ($R^2 = 0.827$). Furthermore, it seemed that the reduction in the yield stress incremented the mini-slump flow diameter. Consequently, a well-defined representation of the yield stress value can be estimated from the mini-slump flow diameter test. The results are consistent with the literature (Çelik et al., 2015; Çınar et al., 2017).

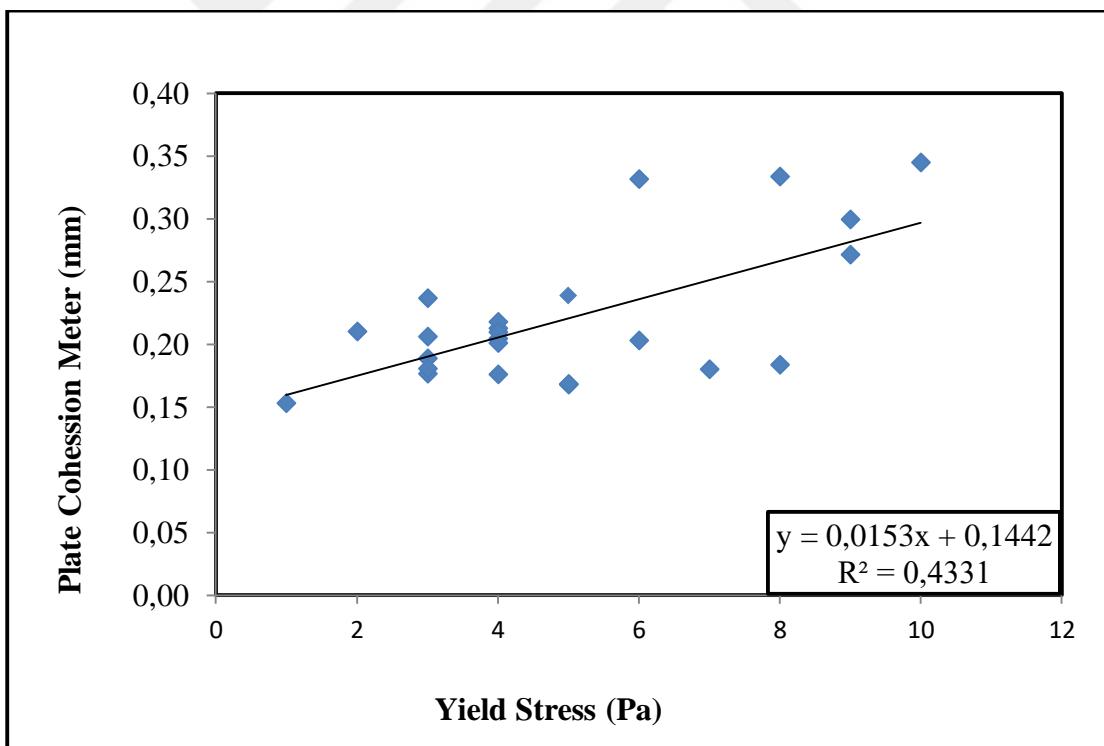

Figures 5.9(b) and 5.9(c) shown the relationship between plastic viscosity and MCFT and yield stress and Lombardi PCM test. In the Figure 5.9(b), it can be obtained that there is a good correlation ($R^2 = 0.869$). Figure 5.9(b) shown that the increment in plastic viscosity increased the MCFT of the CBG mixture. Also, It seemed that there is weak correlation between yield stress and Lombardi PCM test ($R^2 = 0.433$).

5.3.Conclusion

Conclusions of this research work are given below.

- The rheological properties of the CBGs importantly have been improved by the addition of WMP+ FA all percentage of to grout mix at all w/b rates. Strongly shear thickening behavior was got from the CBG mixture all mix WMP+ FA contents
- The increment in the percentage of WMP in the CBG mixture incremented the plastic viscosity.
- According to the control sample, the increment in the percentage of WMP (10-25%) amount increased the mini-slump flow diameter for constant FA (25%) content. Especially, FA increased the fluidity of CBG, when the WMP showed negative effect in increase the MCFT in WMP+FA content.
- The rheological properties (the plastic viscosity and the yield stress) of the CBG got from the modified Bingham model also illustrates a good correlation with the MCFT and mini-slump flow of the CBG ($R^2 = 0.82$, $R^2=0.86$). On the other hand, no correlation was found between yield stress and Lombardi PCM test.
- According to fresh properties test results; Waste Marble Powder and Fly Ash can be suitable for use in substitution cement in proportions up to 20% and %25. For this reason, CO_2 emissions decreased by 45% and cost decreased by this rate.

CHAPTER 6

MECHANICAL PROPERTIES OF SOILCRETE MIXTURES MODIFIED WITH WASTE MARBLE POWDER (WMP) AND FLY ASH (FA)

6.1. Introduction

Grouting is described as the injection of fluid materials into the cavities of the ground or the space between the floor and adjacent structures. The main purpose of the grouting is to produce a denser, less permeable rock or soil, and/or stronger; it may also simply serve to fill voids, which are otherwise inaccessible and may prevent sufficient stress transmission from the floor or from a structure to the ground. As the cement-based grout especially used for jet grouting applications should have low viscosity to easily penetrate into rock or soil, w/c (water/cement) rate ranges 0.6 to 2 (Moseley, 1993). Typical mixes have generally w/c ratios of 1:1 by weight (Coulter and Martin, 2006) to ensure grout of sufficiently low viscosity to fill up the cut soil volume, allowing air voids to escape (Lee et al., 2005). The structural materials obtained by mixing soils with cement slurry from jet-grouting application are called as soilcrete mixtures (Andromalos and Gazaway, 1989).

There have been many studies conducted on jet grouting soilcrete columns prepared with using different types of additives (Clarke et al., 1992; De Paoli et al., 1992; Littlejohn, 1982; Lowe and Standford, 1982; Schwarz and Krizek, 1992; Tinoco et al., 2016). And also, an experimental study has already been conducted by Kolovos, Asteris, Cotsovovs, Badogiannis, and Tsivilis (2013) on the mechanical characters of soilcrete mixs improved with metakaolin. For preparing the mixtures, clay was used as binder in moderate and low proportions in order to simulate typical mixing conditions of practice, in soil stabilisation techniques. Moreover, the possible utilisation of metakaolin as a mineral admixture for the synthesis of sand-based binders that can also be used either as grouts in soil applications or for the production of sandcrete was presented by Kolovos, Asteris, and Tsivilis (2016). Overall, the behaviour of cementations sand-based binders (sandcrete) as a potential structures material was experimentally examined in this study. Also, the impact of the

metakaolin supplementation on the mechanical characterizes (i.e. deformability, strength elasticity modulus, the uniaxial compressive) of sandcrete was investigated and checked to those of traditional concrete in their study. Similarly, investigation of the mechanical behaviour of metakaolin-based sandcrete mixtures was conducted by Asteris, Kolovos, Athanasopoulou, Plevris, and Konstantakatos (2017). Sandcrete mixture design optimisation and mechanical attitude of the manufactured specimens were experimentally researched in this work.

Rheological and mechanical properties of the grout are changed by adding minerals at different proportions. Several minerals such as cement kiln dust, silica fume, metakaolin, and bentonite have been utilized for many studies (Aitcin, Ballivy, & Parizeau, 1984; Bustamante & Gouvenot, 1983; Deere, 1982; Ruggiero, 1984; Weaver, Evans, & Pancoski, 1990). Therefore, the usage of minerals as an admixture in producing grout mix reduces the cost of production, yet it increases the workability and long term performance. However, the effect of WMP and WMP + FA replaced with cement at different proportions on their strength, stiffness, durability and rheological properties has not been thoroughly investigated for higher w/c ratios (greater than w/b = 0.75).

Marble is a very important material for construction, particularly for decoration reasons. %25 percent of marble turns to powder and dust due to shaping, polishing, and sawing. Turkey has 40 percent of the world's total marble and produces 7 million tons of marble were manufactured every year. Five thousand processing factories are used for marble production in Turkey. It is clear that these waste products reach millions of tons; so it is too difficult to store this amount of wastes (Alyamac and Ince, 2009).

The annihilation of Waste Marble Powder (WMP) is one of the most environmental concern all over the world nowadays. On the other hand, WMP can be used to increase the fresh and hardened properties of cementitious grout.

WMP is used like a complementary cement based material in the concrete (Pooja and Prof, 2014). Earlier researches concluded that maximum 10-15 percent of WMP can be conveniently mixed into the concrete without negatively impacting the durability, hardness and strength of the resulting concrete (Shirule et al., 2012; Aliabdo et al., 2014; Rodrigues et al., 2015). Another researches investigated the usage of WMP as

a cement substitution and showed that combining of WMP in self compacting concrete (SCC) with concrete reduce the splitting tensile strength, compressive strength, bulk weight, slump flow, ultrasonic pulse velocity, porosity and cost (Shirule et al., 2012; Aliabdo et al., 2014; Rodrigues et al., 2015; Yao et al., 2015; Uysal and Yilmaz, 2011; Gencel et al., 2012; Gesoglu et al., 2012; Alyousef et al., 2018).

Usually, the percentage of FA usage is 10-35% in concrete (Yao et al., 2015). The usage of FA in concretes and SCC have also been investigated and have been well developed in the last decade (Uysal and Yilmaz, 2011). On the other hand, there is limited knowledge available concerning the fresh characteristics of cement based grout containing FA. The replacement of Portland Cement with FA is important for decreasing the viscosity, increasing passing ability and flowability of cement based grout materials (Gencel et al., 2012).

Their study showed that different replacement level of WMP and FA with cement at different w/b ratios is possible for producing cement base grout. Because of the beneficial effects of WMP and FA have been mentioned above, this waste may be used as an additive for a soilcrete mixture design, to develop the mechanical and rheological behaviour and long term durability of soilcrete as a structural material. Therefore, this study presents the possible utilisation of WMP and FA as an additive for the synthesis of binders that can be used either as grouts in soil applications or for the production of soilcretes that can be utilized in geotechnical applications. And also, the second and third part of this study was conducted on rheological and workability properties of the cement base grout prepared by addition of WMP and FA replaced with cement at same proportions of WMP and WMP+FA and same w/b ratios by. In general, the attitude of soilcrete as a potential construction material has been investigated experimentally. Also, the impact of WMP and WMP+FA on the mechanical characteristics (like the unconfined compressive strength, elasticity modulus, bleeding and failure mechanism) of soilcrete mixtures obtained with different w/b ratios were investigated.

6.2.Experimental procedure

6.2.1. Materials used in this study

In this research Portland cement (CEM I-42.5R) was used complying with ASTM C150 Type-I cement. Class F FA was used an additive in CBG according to ASTM C 618. Also, WMP was utilized as an additive. Waste marble sludge (WMS) was provided in the form of a wet slurry from marble factory in Gaziantep-Turkey. The WMS was dried in an oven at 100 ± 10 °C for 24 hours and then sieved with 150 μm sieve “Fig. 5.1”.

Table 4.1 shows the physical and chemical characteristics of FA, WMP and cement utilized in this study. The clay used in this study was obtained from Gaziantep city in Turkey. The clay soil was collected one meter from the ground surface. The clay was sieved as passing from 75 μm sieve size. Then, laboratory tests related to Atterberg limits, swelling test, standard proctor compaction test made for the clay according to ASTM D4318-05, ASTM D4546-08 and ASTM D698-12, respectively. According to Unified Soil Classification System (USCS) the clay soil is classified as CL (low plasticity clay). Index properties of the clay (including swelling and compaction parameters) are summarised in Table 6.1. The clay had bell-shaped compaction curves obtained from standard compaction test.

Table 6. 1: Index properties and classifications of clay tested.

| Properties | Values |
|------------------------------------|------------------------|
| Liquid limit (LL) | 42% |
| Plastic limit (PL) | 23% |
| Swell per cent | 5% |
| Degree of expansivity | Medium |
| Maximum dry density (MDD) | 1.65 g/cm ³ |
| Optimum moisture content (OMC) | 17% |
| Classification (according to USCS) | CL |

6.2.2. Mixture proportions and preparations

Water–binder (w/b) ratio is one of the important parameters that have considerable impact on hardened and fresh characteristics of grout mixs. The ranges of w/c rate that was applied in the past studies were changed among 0.25 to 0.65. On the other hand, this ratio is preferred for injectable grouting in and rock soils at range of 1.0 and 1.5. Furthermore, this ratio sometimes can reach up to 2.0 for jet grouting

applications. Because of this situation, 0.75, 1.00, 1.25 and 1.5 were selected as water–binder ratio (w/b) for this study in order to evaluate the impact of WMP and WMP+FA on the grout mixtures. These ratios generally used for geotechnical projects like CBG for rock or soil injection, sealing cement grouts and jet-grouting (Moseley,1993). For research the impact of WMP and WMP+FA at different substitutions on the cement- based grout mixtures prepared for this study, forty eight mixtures were produced at different w/b rates that have been mentioned (see Table 6.2). Not only, replacement level of WMP was selected as important parameter, but also w/b ratio was used as significant variable for this study. WMP was replaced with cement at substitutions of 5, 10, 15, 20 and 25% by mass and WMP+FA were replaced with cement at substitutions of 10, 15, 20, 25 and 30% by mass and FA was replaced constant value (%25) in this study. The control mixture was produced at each w/b ratio without WMP and FA additive due to control purposes. The mix design parameters including all substitutions of WMP, WMP+FA and w/b rates are demonstrated in Table 6.2. Most of the studies considered mixes with 4–10% cement contents, more typical of deep mixing than jet grouting (Lee et al., 2005), where according to Kauschinger et al. (1992), jet grouting may have cement contents (rate of the weight of cement to total weight of the mix) of up to 50%. Because of this situation clay content was selected as 20% of total amount of the mixtures (Table 6.2).

Table 6. 2: Mix design of the samples (a.WMP, b. WMP+FA) for 1 kg mix.

In order to obtain grout mix samples, the same mixing procedure was used for all samples. Five-litre standard rotary type laboratory mixer is used to produce the grout mixtures. The mixing method that was selected for this study was applied as following; firstly, the binders that consist of cement and WMP and WMP+FA were obtained by mixing with water for 1 min, and then mixer was stopped and the binders mixed by hand for 1 minute. Subsequently, the clay selected for this study was inserted to the binder mix. Eventually, the mixtures including binders and clay were mixed by the mixer at 240 rpm speed for 3 min. Therefore, the total mixing time was applied as 5 min for preparing all samples in this study. Humidity and temperature of the laboratory for all tests were measured as 55–65% and 23 ± 3 °C, respectively.

6.2.3. Unconfined compressive strength (UCS) test

UCS tests were conducted on the soilcretes prepared from the soils, cement, WMP and WMP+FA mixs following ASTM D5102-09b. The shear rate was chosen as 1 mm/min for all experiments. A total of 432 (2x(24 mixtures × 3 day curing × 3 trial for each mixture)) soilcretes samples were prepared for Unconfined compressive strength (UCS) test in this investigation. All mixtures were cured for 3, 7 and 28 days at dry condition. Each case has been tested for three specimens in order to check the results. Test results showed that all results were repetitive. Therefore, the authors used the average values for this study. In order to compose soilcrete samples plastic molds 110 mm high with a height to diameter ratio of 2:1 according to ASTM D2166-13 (Figure 6.1(a)) were used. The problem of bleed was overcome by attaching cardboard plastic collars to the top of the moulds mostly occurring in the first two hours (Lee et al., 2005). Then, the moulds with collars were covered by plastic bags to prevent escaping of the water that is available in the grout samples. The bleed water was siphoned from the top of the sample and the collar was removed after 24 h. Excess grout was then shaved from the top of the sample in order to bring the level of the sample to the top of the mould. The sample was then left in the mould for a further 24 h before being removed. From the latter curves the uniaxial UCS and elasticity modulus of soilcrete also the axial-strain corresponding to the maximum sustained load were detected. The Uni-axial UCS test machine used for this experiments is demonstrated in Figure 6.1(c). Then, these values were compared to control samples and each other's.

6.2.4. Bleeding test for stabilization of fresh grouts

The stability of CBG mix is decided by basic laboratory tests (bleeding test) utilizing 1000 ml CBG contained in a regular glass cylinder with a constant diameter of 60 mm (Figure 6.1(b)). To assess the stability of a suspension, the sedimentation rate (dV / V), which is defined as the volume of the clear water (dV) which is separated on the suspension divided into the actual slurry volume (ie, $V = 1000$ ml), is recorded. Deere (1982) classified the suspension as a 'stable suspension' based on Kutzner (1996) based on a sedimentation rate of not more than 5% and a rate of less than 10%. High sedimentation ratio is typical of pure CBG and has great practical results because if sedimentation of solids take shape throught grouting, the voids

being treated and the grouting pipelines can be plugged and the grout cannot flow any further.

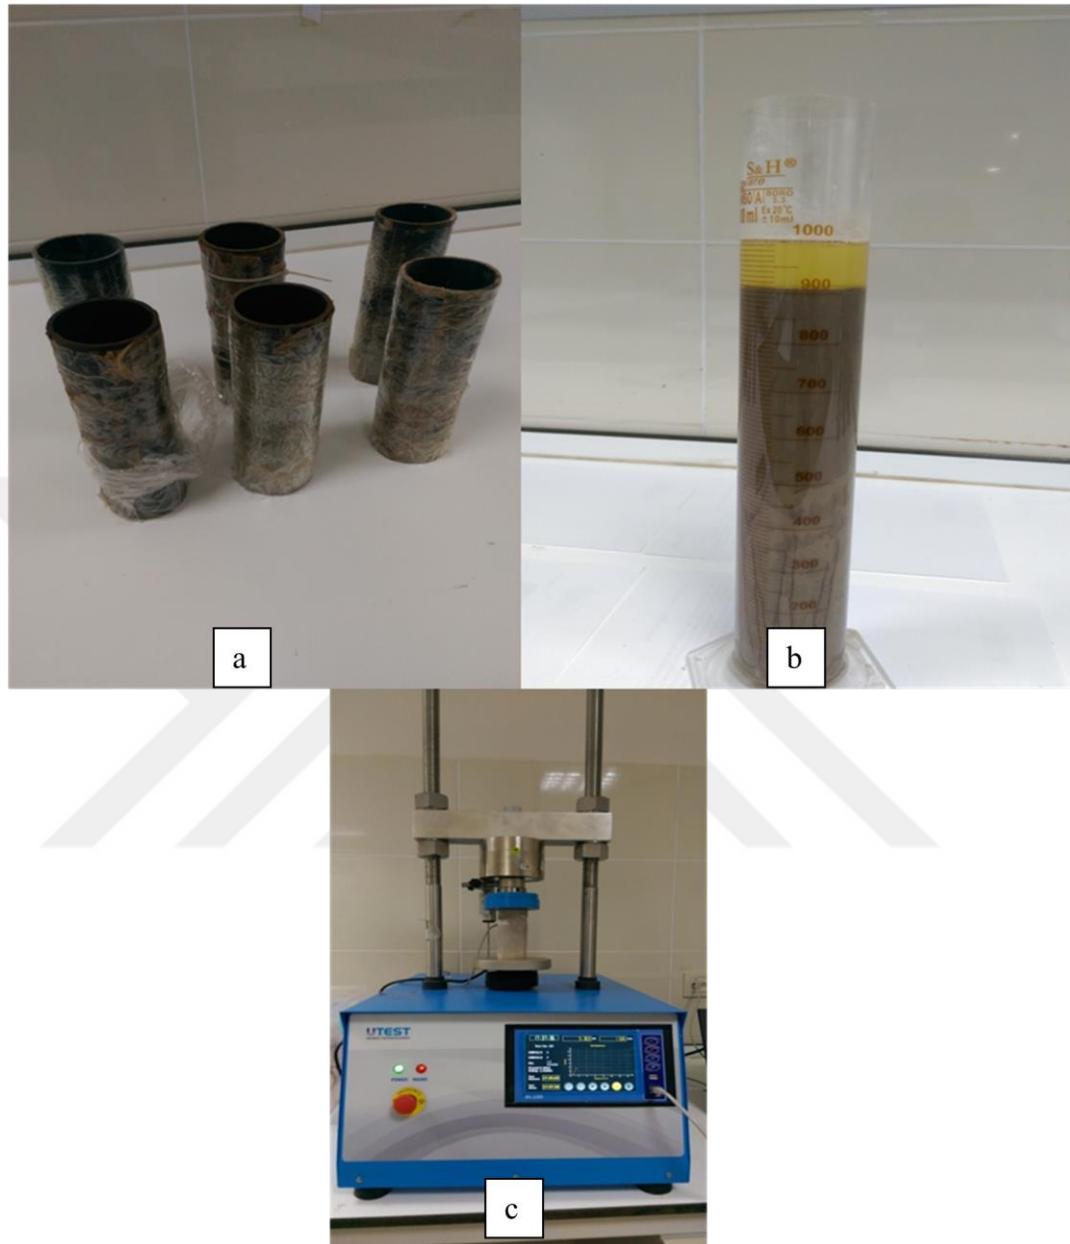

Figure 6. 1: (a) Plastic moulds used for preparing soilcretes. (b) Settlement of M23 mix after bleeding test. (c) The Uni-axial unconfined compressive strength test machine used for this study.

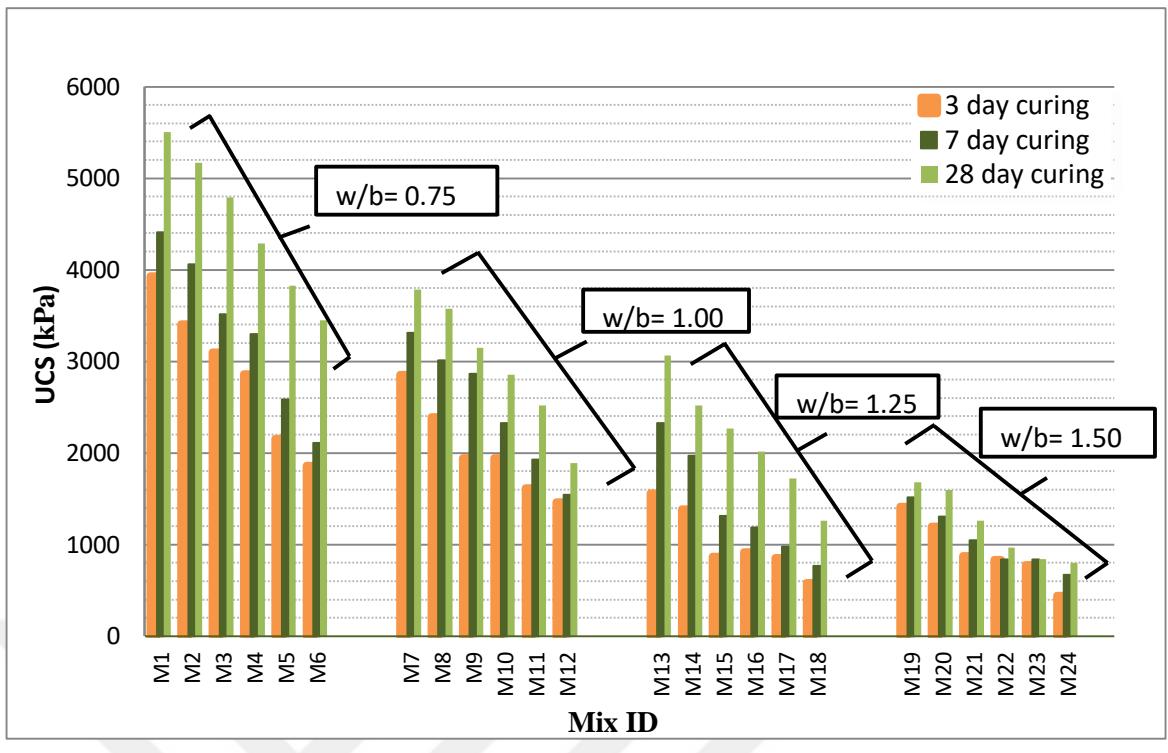

In accordance with the work on pore structure of CBG sand made by Helal and Krizek (1992) by using microfine CG (i.e. MC-500, MC-300 and MC-100), the ratio of original ungrouted pore space occupied by the hydration products and bleed water was found to be a function of w/c rate of CBG. For the more unbalanced CBG with

w/c rate exceeding 1.25 which indicate sedimentation rate greater than 5% during first phase (i.e. <30 min) of test, aggregation and sedimentation of cement grains takes place in soil voids prior to setting with accumulated bleed water occupies the upper parts of the pore void, inducing anisotropic properties in grouted soils.

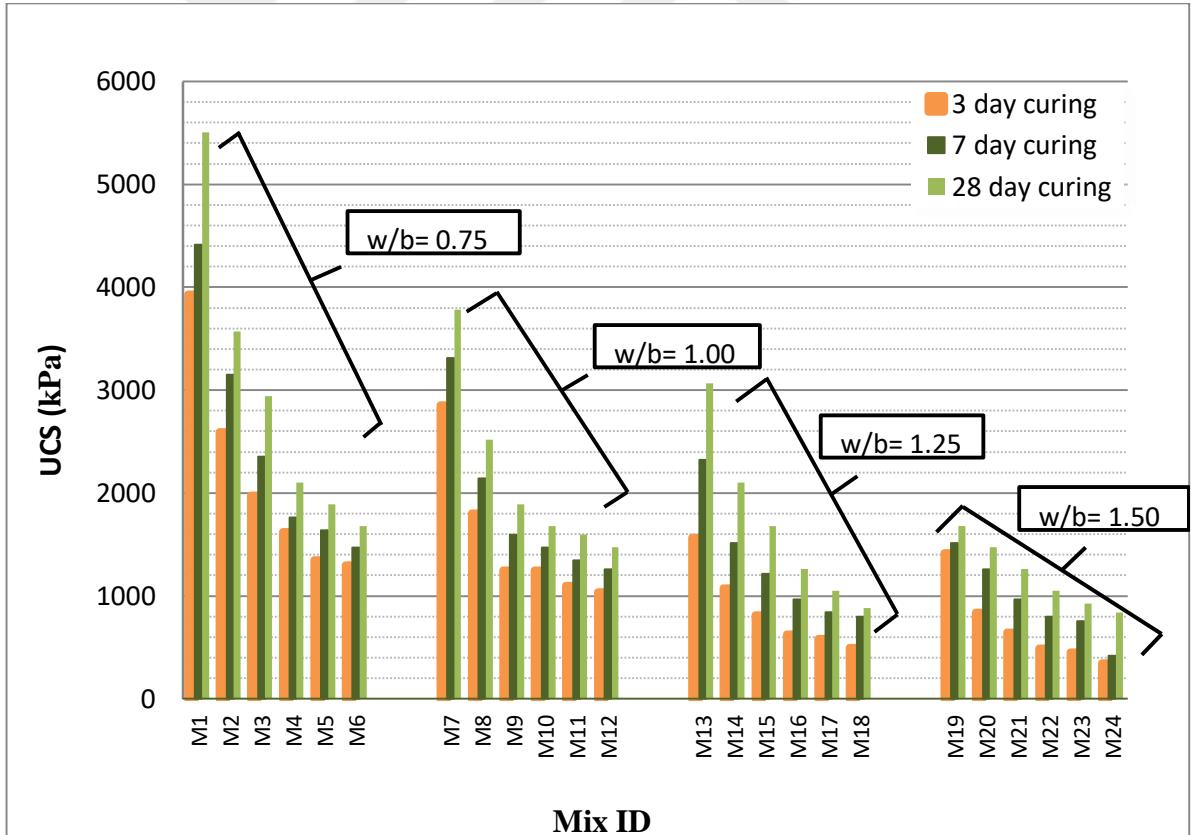

6.3. Results and Discussions

6.3.1. UCS results for WMP and WMP+FA

UCS results of the mixtures prepared by replacing only 5-25% of WMP and 10-30% of WMP and constant 25% of FA with cement at various water/binder rates (0.75, 1.00, 1.25 and 1.5) for 3, 7 and 28 days curing time are given in Figure 6.2. The average UCS results of the mixtures prepared for this study are ranged between 400 kPa and 5,5 MPa and those are very close to the results (between 1 and 15 MPa in range) that were obtained from the similar works reported in the literature. These studies reported in literature are related with not only soil-based building elements but also grouting practices and repair mortars (Consoli et al., 2011; Mikkelsen, 2002; Morel et al., 2007; Nikbakhtan and Osanloo, 2009; Pavlovic et al., 2010a; Pavlovic et al., 2010b; Sonebi et al., 2013; Yoon and Abu-Farsakh, 2009). According to Figure 6.2, high UCS results were obtained because of the addition of WMP for binders at the lower water/binder ratios in comparison to the higher water/binder ratios. UCS of the soilcretes gradually reduces with increment of water/binder ratio. As expected, the higher water/binder rate is, the higher is the decrease for the calculated average UCS of soilcrete specimens at all curing times (Kolovos et al., 2013). The supplement of WMP in the binder ensued in lower values for the found average compressive strength of soilcrete specimens at all curing times, in comparison to the reference specimens (M1, M7, M13 and M19). The increment in the compressive strength of soilcretes is quick early in the curing time and then slows down over time (Porbaha et al., 2000). As a result it is clearly seen that WMP could be used as an additive for improvement of problematic clay soils.

b. WMP+FA

Figure 6. 2: Compressive strength of all soilcrete samples at 3, 7 and 28 days (at different w/b ratios; .75, 1.00 and 1.25, respectively) a.WMP, b. WMP+FA

As it is clearly seen in Figure 6.3, Figure 6.4, Figure 6.5, Figure 6.6, Figure 6.7, Figure 6.8, Figure 6.9, and Figure 6.10 with increasing amount of WMP and WMP+FA in soilcrete sample UCS value of all soilcretes decrease at all curing days and w/b ratios. This consistent model for all the composites is described in Ettu et al. (2013e), as a result of low pozzolanic reaction rate in early ages. The silica from the pozzolans is produced by reacting with the lime produced as the hydration product of ordinary portland cement to produce additional calcium-silicate hydrate, which increases the binder efficiency and strength values at later days of curring (after 50 days curing). The max UCS value in soilcrete sample was observed as 6 Mpa when constitution of WMP and WMP+ FA was 0% at w/b 0.75 and 28 day curing. On the other hand the min UCS of the samples was determined as (WMP) 500 kPa and (WMP+FA) 250 kPa.

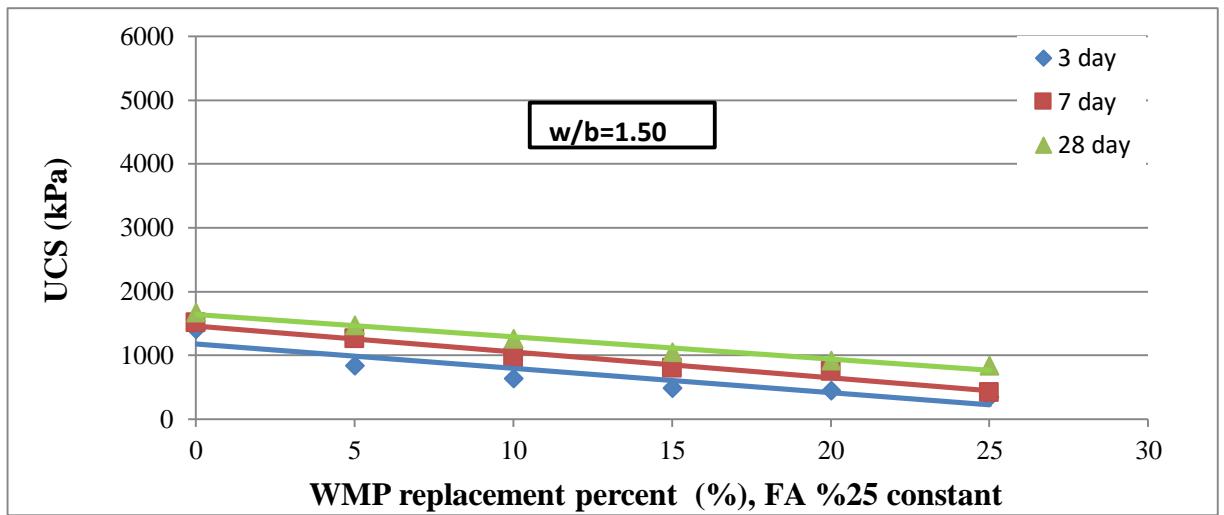

Figure 6. 10: UCS results of soilcrete samples at 3,7 and 28 days for $w/b= 1.50$ and various WMP+FA (constant %25) replacement levels

The compressive strengths of soilcretes obtained in this study found significantly increased with increasing curing time as it is shown in Figure 6.11, Figure 6.12, Figure 6.13, Figure 6.14, Figure 6.15, Figure 6.16, Figure 6.17, Figure 6.18. (Kawasaki et. al. 1981; Uddin et. al. 1997)

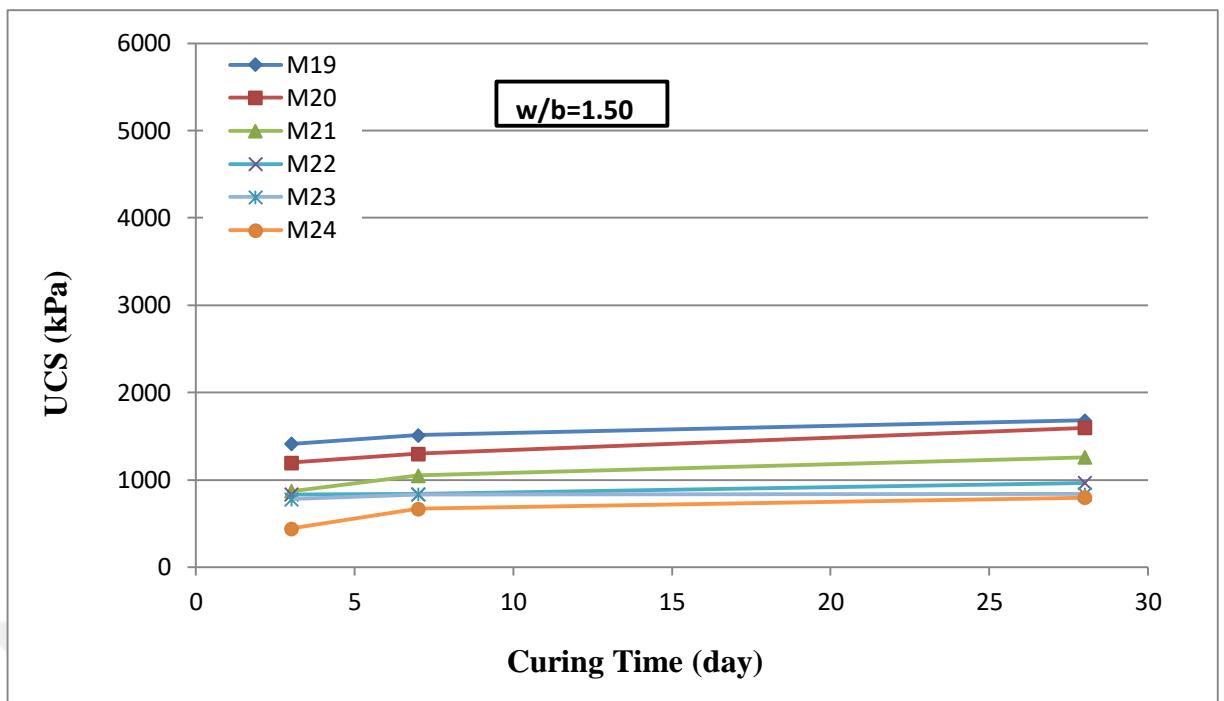

Figure 6. 14: UCS-curing time relations for WMP and w/b= 1.50

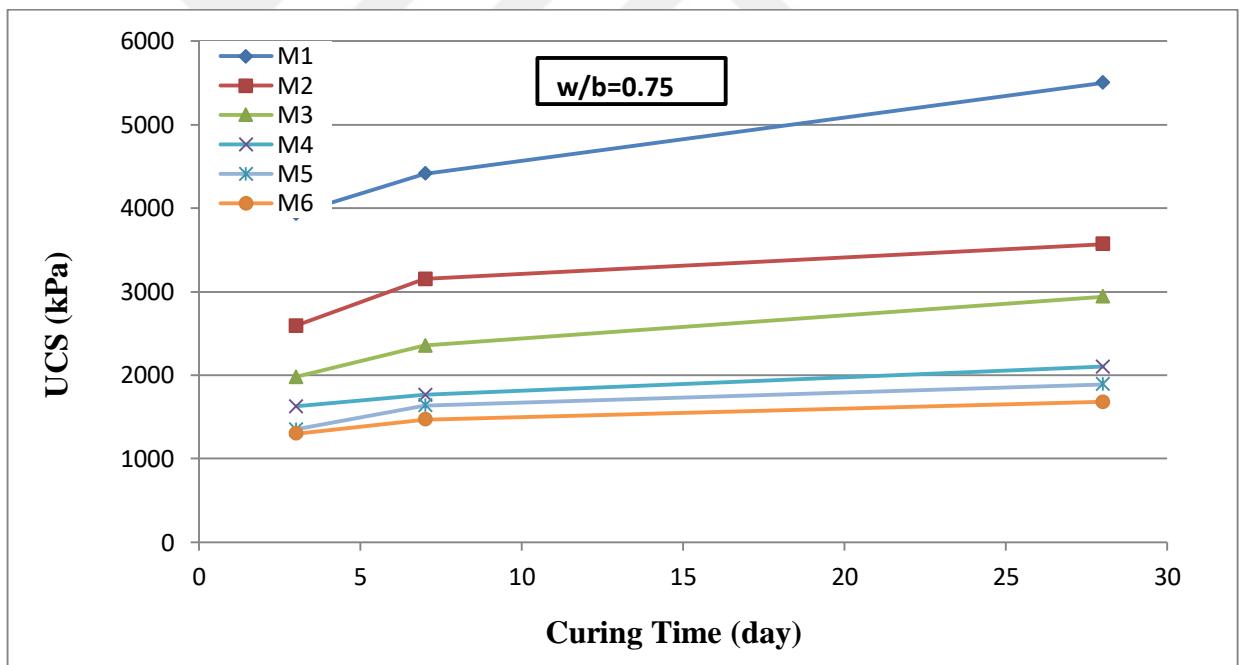

Figure 6. 15: UCS-curing time relations for WMP+FA(constant %25) and w/b= 0.75

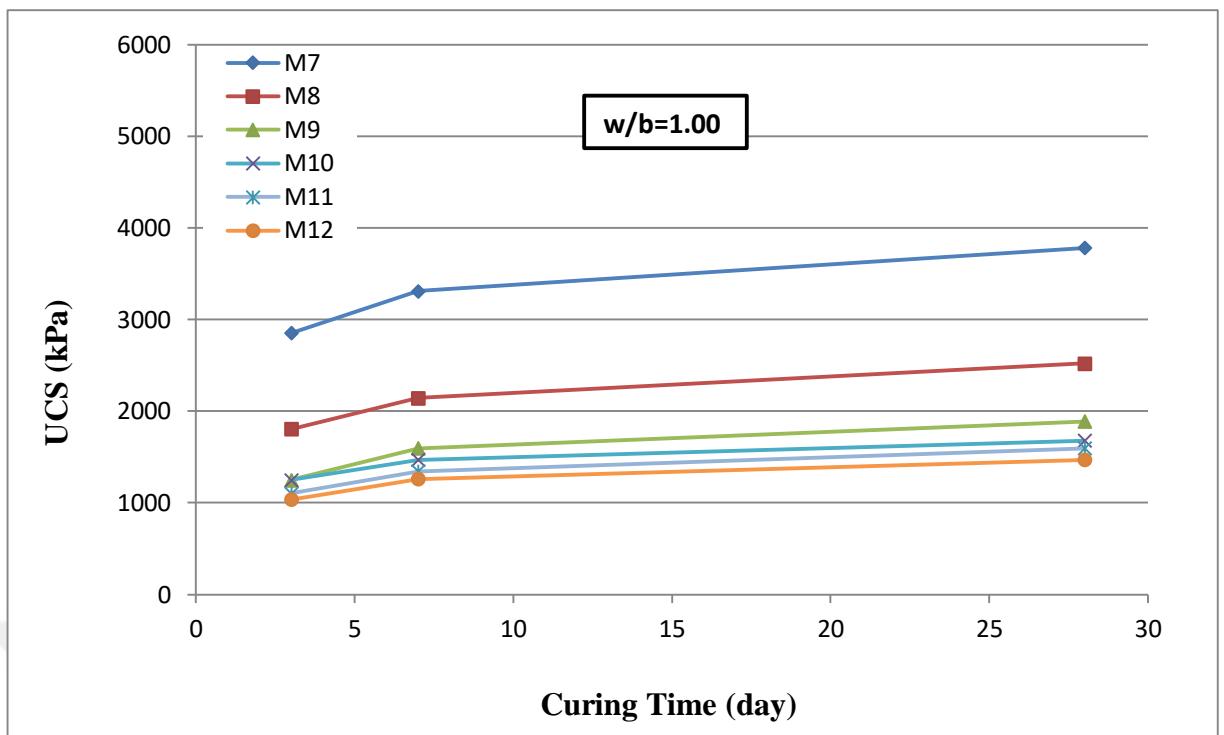

Figure 6. 16: UCS-curing time relations for WMP+FA(constant %25) and w/b= 1.00

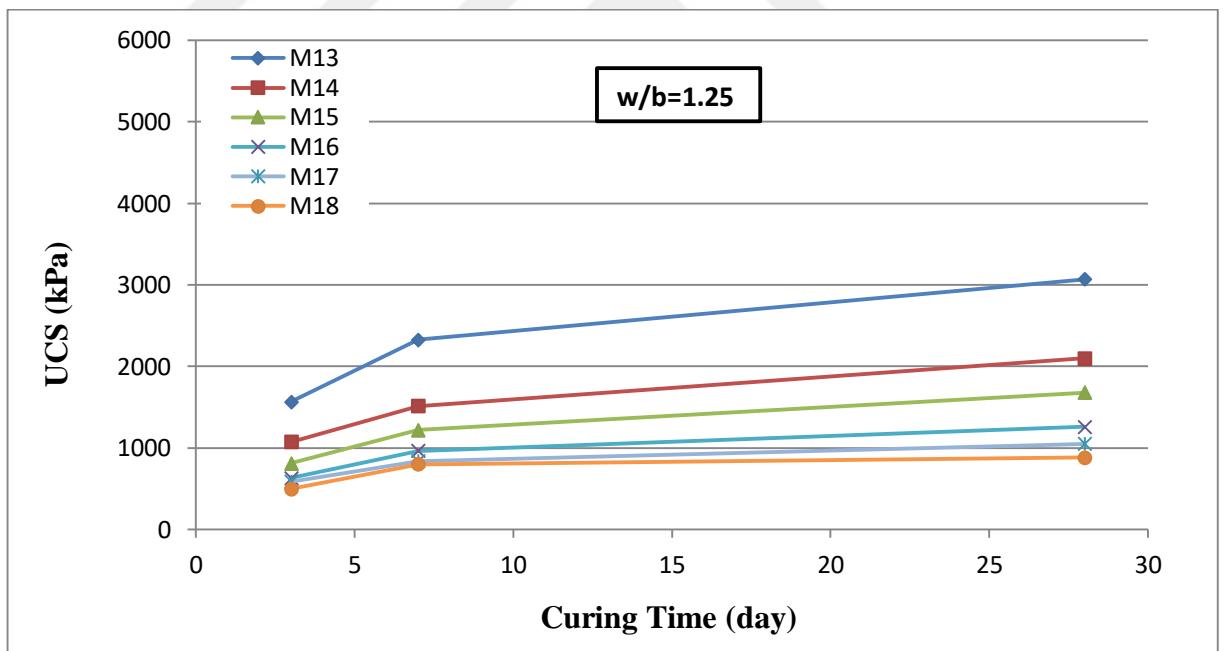

Figure 6. 17: UCS-curing time relations for WMP+FA(constant %25) and w/b= 1.25

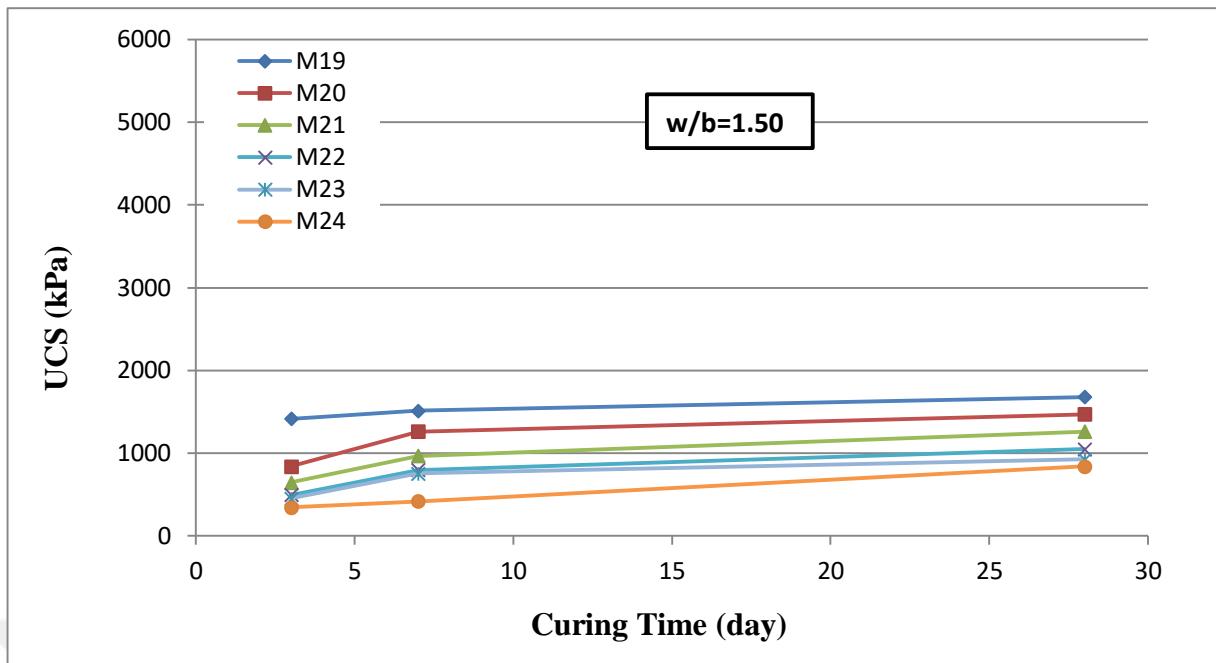

Figure 6. 18: UCS-curing time relations for WMP+FA(constant %25) and w/b= 1.50

The increment in the compressive strength of soilcretes is fast early in the curing time and then slows down over time (Porbaha et al., 2000). For all 28 day curing time ucs values of all soilcretes are greater than 1 Mpa (Figure 6.11, Figure 6.12, Figure 6.13, Figure 6.14, Figure 6.15, Figure 6.16, Figure 6.17, Figure 6.18). Due to the fact that 1 Mpa compressive strength values can be supposed as higher values for stabilizing the problematic soils in geotechnical practices (Hausmann, 1990), it is clearly seen that WMP and WMP+FA could be used as an additive for improvement of problematic clay soils.

As it is known that the compressive strength of a clay–cement mix usually increments because of enhancement the cement ingredient up to a certain percentage, however its strength starts to decrease after which (Uddin et al., 1997). Uni-axial compressive strength of the soilcretes is generally ranged from 10 to 50 times the UCS of the natural soils. The upper and lower limits of the strength enhancement were got for higher cement ingredients and/or non-adhering soils, also for lower cement ingredients and/or adhesive soils, respectively (Jaritngam and Swasdi, 2006). Figure 6.19, Figure 6.20, Figure 6.21, Figure 6.22, Figure 6.23, and Figure 6.24 demonstrates the similar behaviour with respect to increasing of cement content in soilcretes comparing with the literature mentioned above. Test results showed that cement content had an important influence because of increasing compressive

strength of the mixs at all w/b ratios and curing time. The increasing ranges are same for all curing time and w/b ratios.

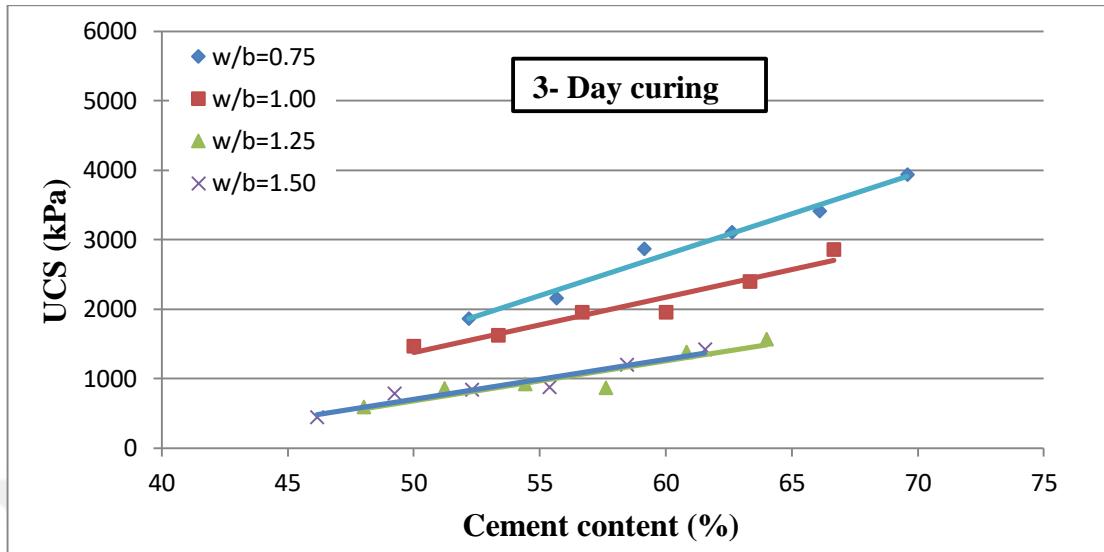

Figure 6. 19: UCS-cement content relations at all w/b ratios for 3 day curing (WMP)

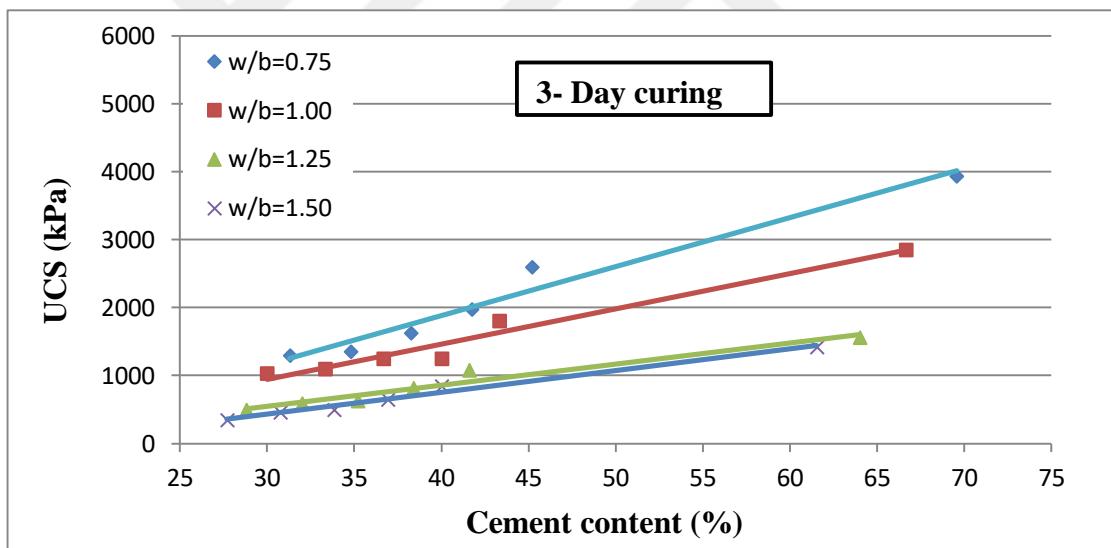

Figure 6. 20: UCS-cement content relations at all w/b ratios for 3 day curing (WMP + FA)

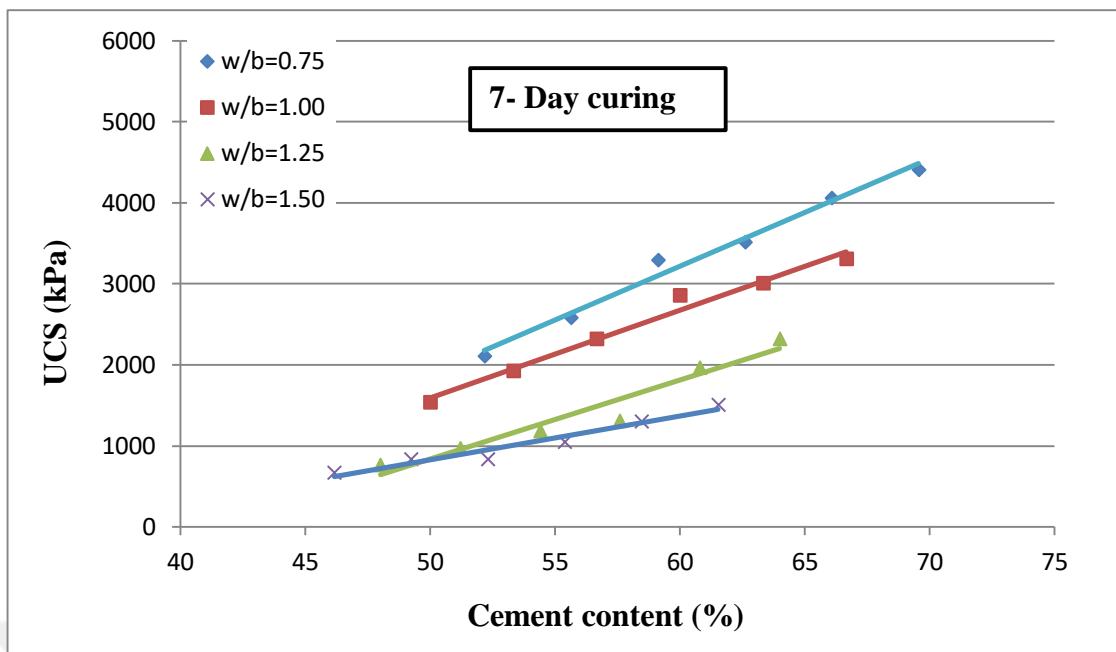

Figure 6. 21: UCS-cement content relations at all w/b ratios for 7 day curing (WMP)

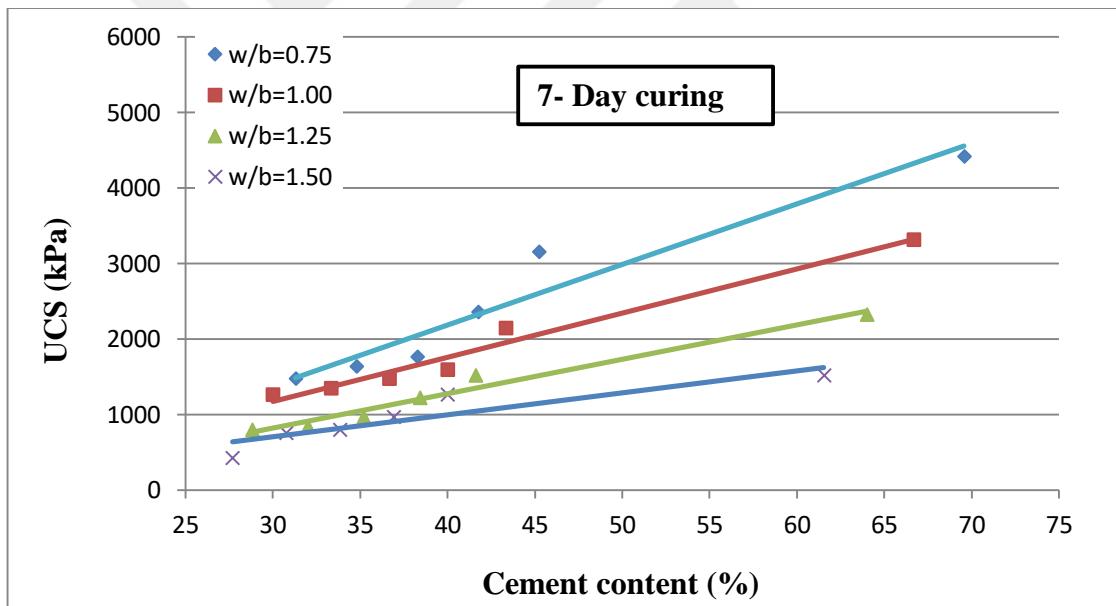

Figure 6. 22: UCS-cement content relations at all w/b ratios for 7 day curing (WMP + FA)

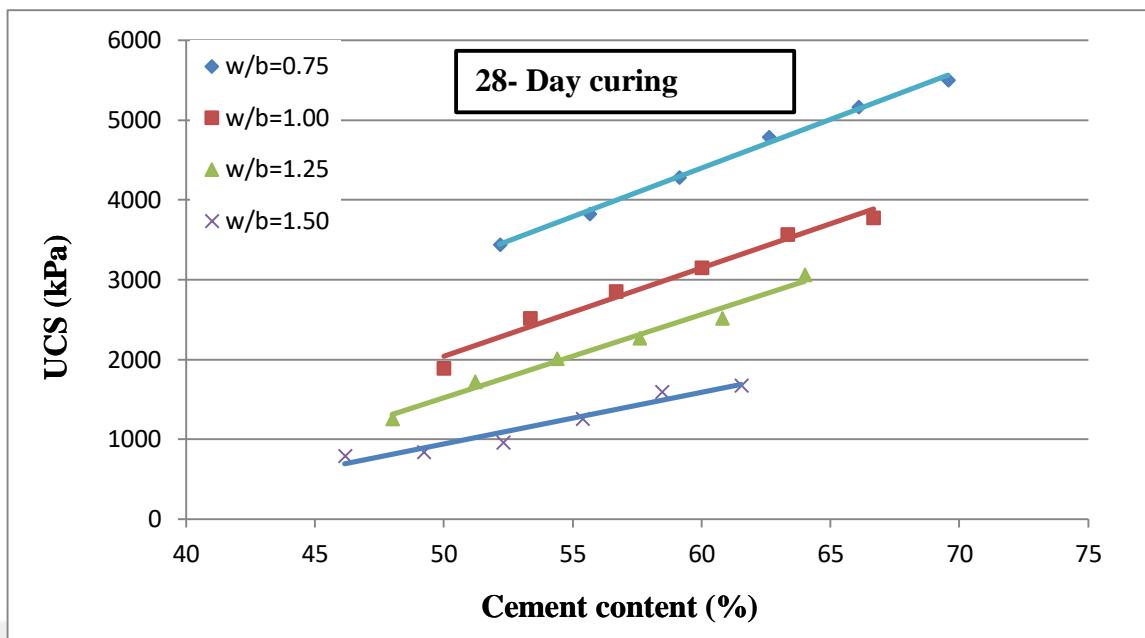

Figure 6. 23: UCS-cement content relations at all w/b ratios for 28 day curing (WMP)

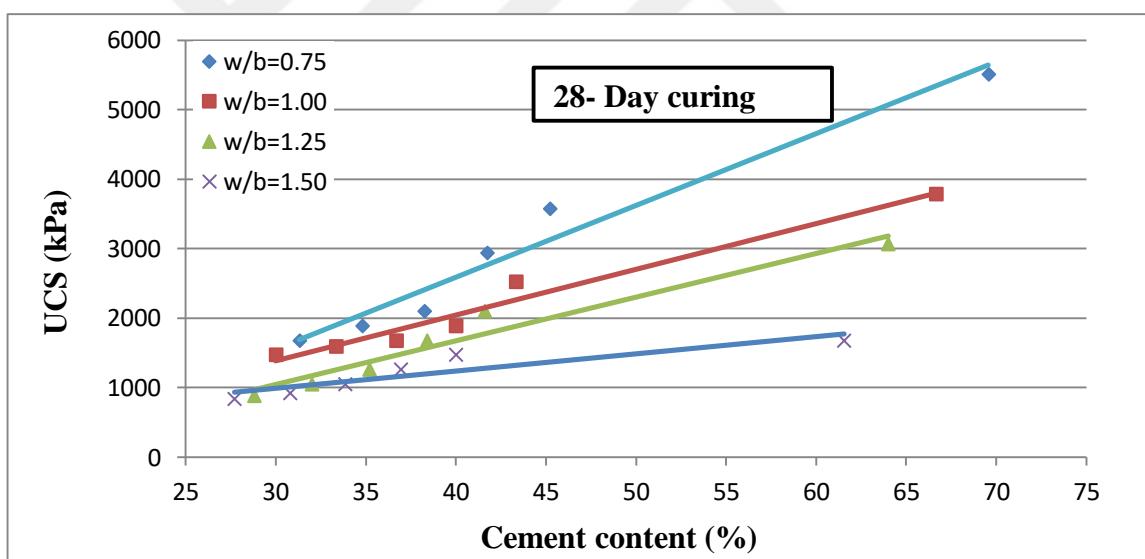

Figure 6. 24: UCS-cement content relations at all w/b ratios for 28 day curing (WMP + FA)

The water–binder ratio is supposed as an important parameter effecting the mechanical properties of cement–clay mixtures (Miura et al., 2001). UCS of clay–cement mixtures reduces remarkably because of increasing of the initial water amount of natural soil. The impact of the cementing agent, by which the strength of the clay–cement mixture is controlled, is generally affected by water–cement ratio (w/c). More cement amount is required by higher initial water content in order to

attain any important impact during the stabilisation of the clay. As it is known in general that UCS importantly reduces with increasing w/c rate of a clay–cement mixture (Hassan, 2009; Miura et al., 2001). In Figure 6.25 w/c rates were given different from w/b ratio. Different w/c ratios were used in this study as it is shown in Table 6.2. This behaviour can be clearly seen also from the results obtained in this study as shown in Figure 6.25. Therefore, increasing of w/c ratio from 0.75 to 2.00 and 0.72 to 3.35 decreased the UCS of the soilcretes samples at 28 day curing time.

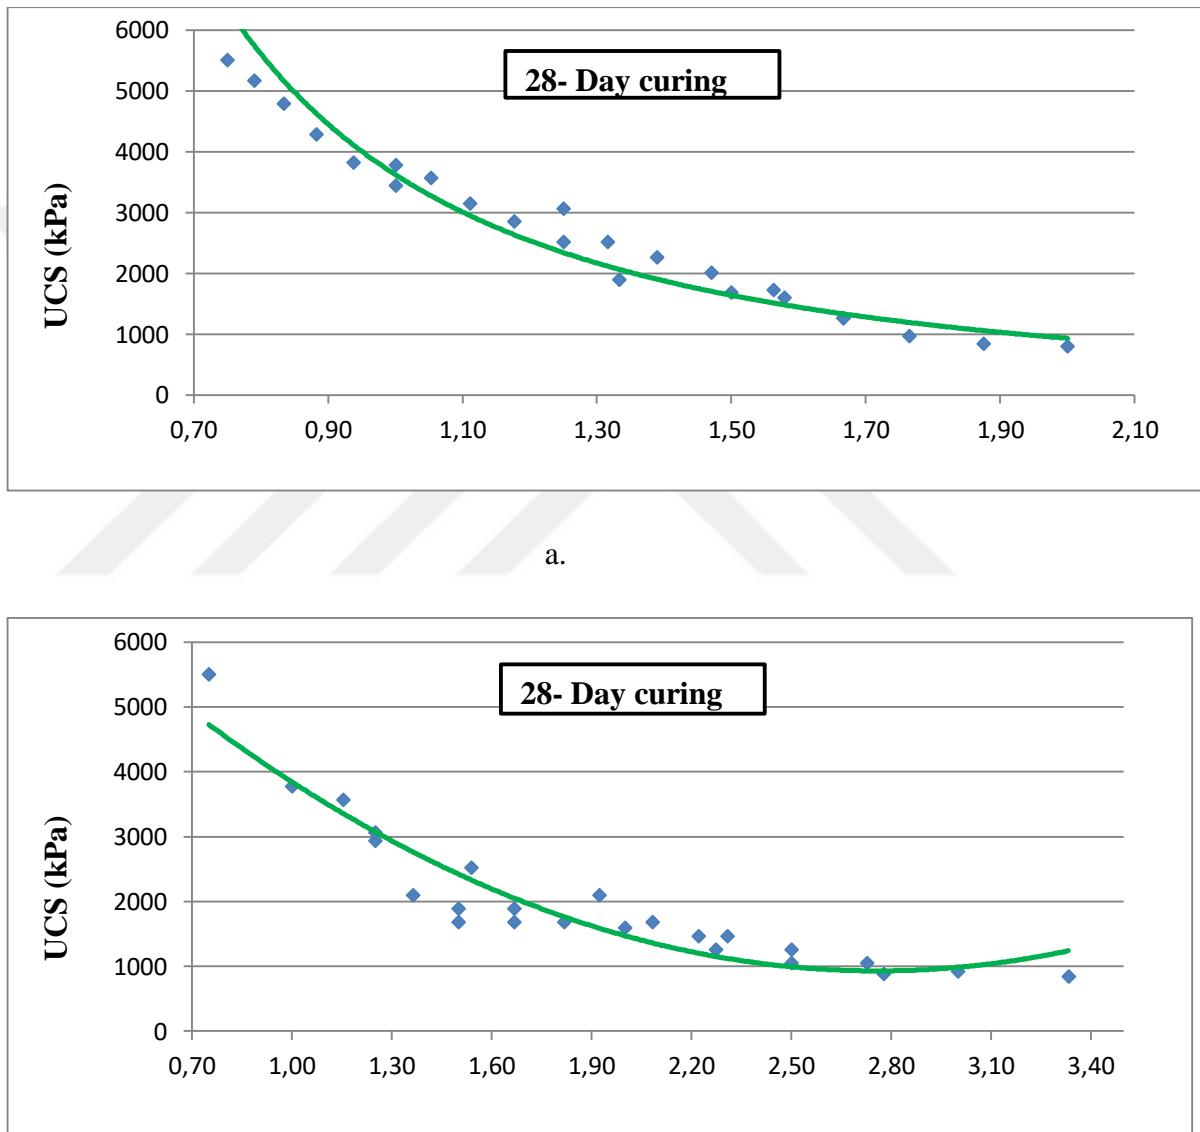

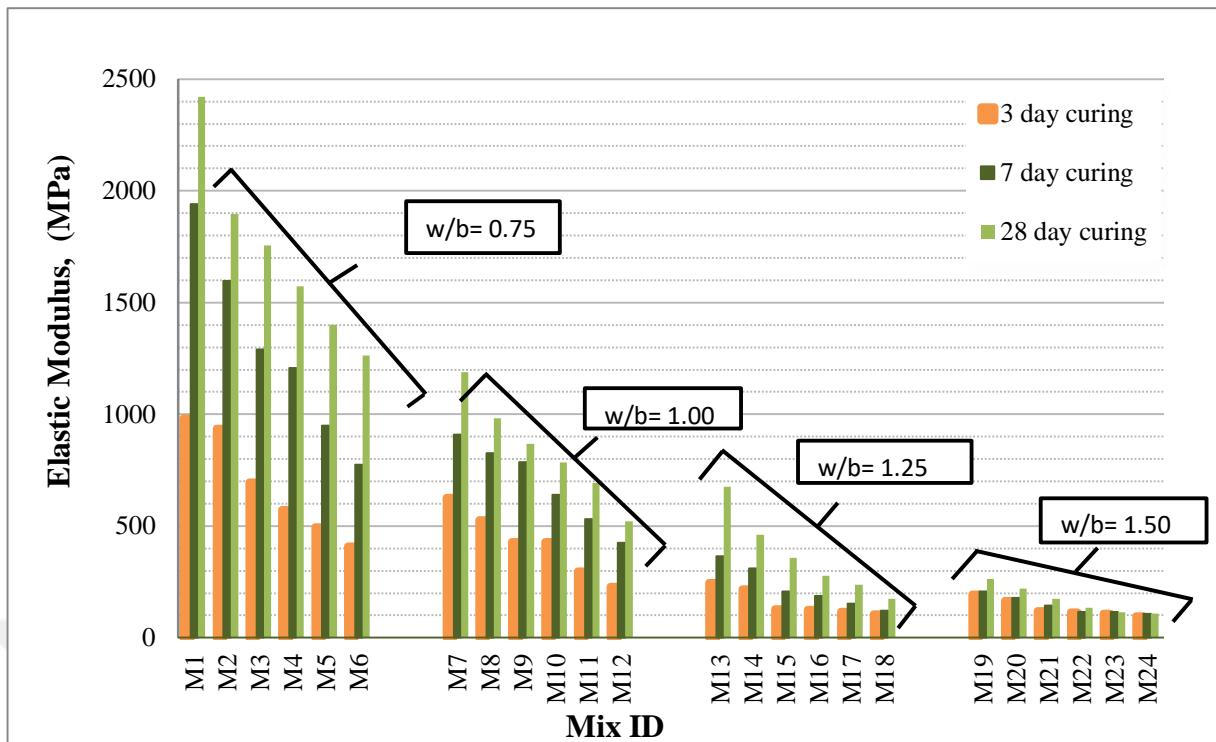

Figure 6. 25: UCS-water/cement ratio relations for all mixtures at 28 day curing a. WMP b. WMP+FA

6.3.2. Elastic modulus results of the soilcretes

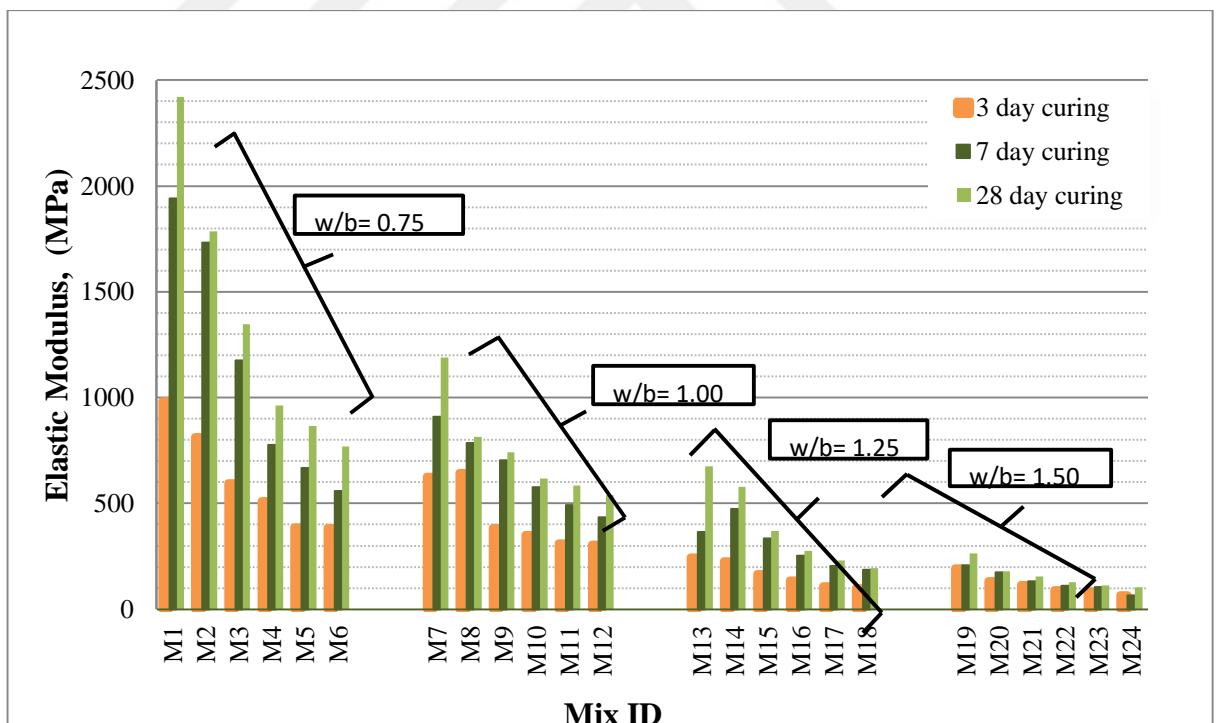

The elastic modulus results of all soilcrete samples at 3,7 and 28 days (a. WMP, b. WMP+FA at various water/binder rates; 0.75, 1.00, 1.25 and 1.50 respectively) are presented in Figure 6.26. All elastic modulus values of the soilcrete samples were obtained from the stress-strain curves of the specimens resulted from the UCS test.

For the low water/binder rate, the supplement of WMP and FA in the binder resulted in higher values for the modulus of elasticity than the reference samples. Elastic modulus changing range with respect to w/b ratio, curing time and WMP and FA amount is similar to UCS behaviour of the soilcretes sample. These soilcretes include much more amount of clay samples. This may cause more brittle behaviour. Figure 6.27 shows the all curing-day modulus of elasticity of the soilcretes in relation to the UCS. As it visible clearly, though there is some scatter around the optimal line, the impact of soil-binder ratio is less pronounced.

This is likely due to the impacts of w/b rate. As illustrates in Table 6.3, the E/qu ratios from soilcrete samples were lower than the suitable amount from the slurry clay–cement mixtures given by Lee et al. (2005). The E/qu ratio of soilcretes for all curing time and w/b ratio were also somewhat similar to values reported in deep cement mixing studies ranging from 130 to 500 (Asano et al., 1996; Futaki et al., 1996). As it is clearly seen Figure 6.27 that modulus of elasticity of the mixtures (E_o) exponentially increases with increase of UCS of samples protected in this study. There is a slightly correlation between UCS value of the mixtures and elastic modulus. The behavior and ranges of the mixtures are repetitive with literature. Also, E/qu values of all mixtures at 3,7 and 28 day curing time decreases with increasing of w/b ratio.

| at w/b=1.00 | 208 | 275 | 283 |
| at w/b=1.25 | 153 | 157 | 170 |
| at w/b=1.50 | 144 | 140 | 142 |

b. WMP+FA

| Condition of Soilcrete samples | Avarage E ₀ /q _u | | |
|--------------------------------|--|--------------|---------------|
| | 3 day curing | 7 day curing | 28 day curing |
| at w/b=0.75 | 288 | 463 | 461 |
| at w/b=1.00 | 282 | 351 | 347 |
| at w/b=1.25 | 192 | 238 | 232 |
| at w/b=1.50 | 164 | 139 | 130 |

6.3.3. Bleeding test results of the soilcretes

The bleeding test results of all mixtures at all w/b ratios and curing days was checked. According to the test results, the increment of water/binder rate increases the settlement of the mixtures. Moreover, bleeding value of the mixtures reduces incorporating with WMP for w/c = 1.25 and 1.5. Because of having a higher surface area of WMP and FA comparing to cement, WMP can absorb much more amount of water than amount of cement. Hence, increasing of WMP and FA amount in the mixtures led to decrease the settlement that was observed as soon as mixing procedure had been completed. The settlement of M23 mixture that was obtained after the bleeding test was completed is clearly seen in Figure 6.1(b).

Figure 6. 28: Failure criteria of the soilcretes samples for 28 day curing. (WMP)

Figure 6. 29: Failure criteria of the soilcretes samples for 28 day curing (WMP+FA)

6.3.4. Failure models after UCS tests for the soilcretes

Brittle crystalline materials contain initial damage, micro cracks, etc. and under compression (e.g. UCS), undergo a complex sequential process of crack closure, crack initiation, stable crack growth, and unstable cracking and eventually fail (Bieniawski, 1989; Brace et al., 1966; Eberhardt et al., 1998; Jaeger et al., 2007; Lajtai and Lajtai, 1974; Li et al., 2003). Many works have been conducted to investigate the failure patterns in sort of cementitious materials under UCS test (Jaeger and Cook, 1979; Klein and Polivka, 1958; Santarelli and Brown, 1989). According to this study, test results are very closed to each other. Cementitious materials generally fail as axial splitting after UCS test is conducted. The failure modes of rock materials obtained from UCS test may maintain beneficial information such as safety and economic conditions for design of different engineering works. A total of 432 soilcretes samples were tested with UCS in this study. Different examples of failure were observed in soilstone samples (Figure 6.28, Figure 6.29). The test results showed that most specimens failed along foliations. In this study, similar failure modes observed in all types of soilcretes are shown as axial splitting. There are various failure behaviours for materials under compressive loads (i.e. shearing along a single plane, Y-shaped, along foliation, multiple fracturing, double shear, and axial splitting). Due to the fact that the soilcretes that were produced from cementitious materials generally are broken as axial splitting type after axial loading (Basu et al., 2013) any effect, which was derived from increasing of w/b ratio and curing time, on the failure models of the soilcrete samples could not be observed clearly (see Figure 6.28, Figure 6. 29).

6.4. Conclusion

Several findings that have been concluded from this study were given as following; The UCS test results of the mixtures prepared for this study were observed at the range of 400 kPa and 5.5 Mpa. These results are seen very similar to the results that were obtained from the past studies. And also, as it is clearly seen from the test results, the UCS values of the samples for 28 day curing are higher than 1 Mpa except 1.5 w/b ratio. As it is known that 1 MPa compressive strength value for soils is accepted as higher value and these types of soils are known as very stiff soils. Therefore, this study shows that WMP and FA could be used as mineral additives in grouting applications for improvement of very soft soils. On the other hand, the E/qu ratio obtained from soilcrete mixtures was less than the corresponding value from

slurry clay–cement mixtures. The E/qu ratio of soilcretes for all curing time and w/b ratio were also somewhat similar to noticed rates in deep cement mixing experiments ranging from 150 to 500. The settlement of the mixtures increased with an increase amount of w/b ratio; however, these bleeding values decreased with an increase of WMP and FA amount. Thus, all bleeding test results are lower than the level of .5%. This means that the stability of all mixtures prepared for this study seems to be in acceptable range. Most of the mixtures prepared for this study failed along foliations. This is the expected behaviour for these types of materials. In this study, similar failure modes observed in all types of soilcretes are indicated as axial splitting.

CHAPTER 7

CONCLUSIONS AND RECOMMENDATIONS

7.1. Conclusion

The results have inferred from this study was given as following;

- The rheological properties of the CBGs importantly have been improved by the addition of WMP to grout mix at various w/b ratios. Strongly shear thickening attitude was got from the CBG mixture the all w/b ratios and all WMP content.
- The increment in the percentage of WMP in the CBG mixture incremented the plastic viscosity at all w/b proportion. Moreover, the increase in w/b rate reduced the viscosity of the CBG for all WMP content.
- The increment in the percentage of WMP in the grout mixture reduced the mini-slump flow diameter. In a constant the percentage of WMP, the increment in water-binder rate incremented the mini-slump flow diameter because of the impact of water. Moreover, the MCFT reduced with an increase in water - binder ratio for a constant waste marble powder content. The workability and flowability of the CBG importantly changed with the increase in the water-binder rate in CBG containing WMP.
- The rheological characteristics (the plastic viscosity and the yield stress) of the CBG got from the modified Bingham model also illustrates a good correlation with the MCFT and mini-slump flow of the grout ($R^2 = 0.83$, $R^2=0.84$). On the other hand, no correlation was found between yield stress and Lombardi PCM test.
- The rheological properties of the CBGs importantly have been improved by the addition of WMP+ FA all percentage of to grout mix at all water/binder rates. Strongly shear thickening attitude was got from the CBG mixture all mix WMP+ FA contents
- The increment in the percentage of WMP in the CBG mixture incremented the plastic viscosity.

- According to the control sample, the increment in the percentage of WMP (10-25%) amount increased the mini-slump flow diameter for constant FA (25%) content.
- Especially, FA increased the fluidity of CBG, when the WMP showed negative effect in increase the MCFT in WMP+FA content.
- The rheological properties (the plastic viscosity and the yield stress) of the CBG got from the modified Bingham model also illustrates a good correlation with the MCFT and mini-slump flow of the CBG ($R^2= 0.82$, $R^2= 0.86$). On the other hand, no correlation was found between yield stress and Lombardi PCM test.
- The UCS test results of the mixtures prepared for this study were observed at the range of 400 kPa and 5.5 Mpa. These results are seen very similar to the results that were obtained from the past studies.
- As it can be concluded from the study, for the lower water/binder rate, the addition of WMP in the binder resulted in higher values in comparison to the higher water/binder rates. When w/b ratio increases, the UCS of the soilcretes gradually decreases. As expected, the higher w/b ratio is the higher is the reduction for the calculated average compressive strength of soilcrete samples at all curing days.
- The supplement of WMP in the binder ensued in lower values for the found average compressive strength of soilcrete specimens at all curing times, in comparison to the reference specimens (M1, M7, M13, M19)
- With an increasing amount of WMP and WMP+FA in soilcrete samples at all curing soilcretes decrease at all curing days and w/b ratios. This consistent pattern for all the composites has been explained as being a result of the low rate of pozzolanic reaction at those early ages.
- The maximum UCS value in soilcrete samples was observed as 6 Mpa when constitution of WMP was 0% at w/b 0.75 and 28 day curing. Moreover the minimum UCS of the samples was determined as 400 kPa for WMP, 250 kPa for WMP+FA.
- The compressive strength of soilcretes obtained in this study have been found to increase significantly with increasing curing time. The increase in the compressive strength of soilcretes is rapid early in curing period and then slows down over time.

- It is clearly seen from the test results, the UCS values of the samples for 28 day curing are higher than 1 Mpa except 1.5 w/b ratio. As it is known that 1 MPa compressive strength value for soils is accepted as higher value and these types of soils are known as very stiff soils. Therefore, this study shows that WMP and FA could be used as mineral additives in grouting applications for improvement of very soft soils.
- Test results showed that cement content had an important influence because of increasing compressive strength of the mixtures at all w/b ratios and curing time. The increasing ranges are same for all curing time and w/b ratios.
- According to this thesis, increase of w/c ratio of the grout mixtures dramatically reduced the compressive strength of the mixtures same as the literature mentioned before chapters.
- While w/c ratio was increasing from 0.7 to 3.3, UCS of soilcretes samples at curing 28 day exponentially decreased and at high w/c ratios reduction range in ucs started to change slightly. This means that high w/c ratios have very little effect on compressive strength of grout mixtures.
- On the other hand, the E/qu ratio obtained from soilcrete mixtures was less than the corresponding value from slurry clay–cement mixes. The E/qu ratio of soilcretes for all curing time and w/b ratio were also somewhat similar to reported values in deep cement mixing studies, which ranged from 150 to 500.
- Modulus of elasticity of the mixtures exponentially increases with increase of unconfined compressive strength of samples produced in this study. There is direct relation between unconfined compressive strength value of the mixtures and elastic modulus.
- The settlement of the mixtures increased with an increase amount of w/b ratio; however these bleeding values decreased with an increase of WMP and FA amount. Thus, all bleeding test results are lower than the level of .5%. This means that the stability of all mixtures prepared for this study seems to be in acceptable range.
- Most of the mixtures prepared for this study failed along foliations. This is the expected behaviour for these types of materials. The similar failure modes observed in all soilcretes types in this study are shown as axial splitting.

- According to fresh and hardened properties test results; Waste Marble Powder can be suitable for use in substitution cement in proportions up to 15% for w/b ratios below 1.25. Also, Waste Marble Powder and Fly Ash can be suitable for use in substitution cement in proportions up to 20% and %25 for w/b ratios below 1.25. For this reason, CO₂ emissions and cost decreased by this total rate.

7.2. Recommendations

The thesis work results demonstrate that WMP using as a filler additive and FA using as a pozzolanic additive for modifying the cementitious grout is an significant work. This experimental study can be enlarged depending on application field study. In any geotechnical work real permeation or jet grout columns can be produced with the cement based grouts incorporating with WMP and FA at various w/b ratios. And then, the soilcretes samples can be taken from the permeton or jet grout columns. Also, mechanical characters of soilcretes can be examined comparing with laboratory test conducted. Moreover, the rheological characters (especially viscosity and workability) of the grout mixtures incorporated with WMP and FA at various w/b ratios can be observed and comparing with experimental results.

CURRICULUM VITAE

PERSONAL INFORMATION

Name and Surname: Muhammet ÇINAR

Natioality: Turkish

Birth place and date: DENİZLİ / 11.09.1989

Phone number: +90 545 464 89 89

Email: muhamed.cinar@hku.edu.tr and mcinar.ce@gmail.com

EDUCATION

| Graduate school | Year |
|--|------|
| Master: Hasan Kalyoncu University (Occupational Health and Safety) | 2017 |
| Master: Hasan Kalyoncu University (Civil Engineering) | 2015 |
| Bachelor: Gaziantep University (Civil Engineering) | 2013 |
| High School: Durmuş Ali Çoban High School | 2006 |

WORK EXPERIENCE

| | Place | Enrollment |
|---------------|---------------------------|---------------------|
| 2014- Present | Hasan Kalyoncu University | Teaching Assistant |
| 2013-2014 | TÜBİTAK 1001 | Researche Assistant |

PUBLICATIONS

Articles:

Çınar, M., Çelik, F., Çanakçı, H., Nassani, D.E. (2017). “Fresh Properties of Cementitious Grout with Rice Husk Powder”. Arabian Journal for Science and Engineering **42 (9)**, 3819-3827 (SCI-Exp)

Çınar, M., Karpuzcu, M., Çanakçı, H. (2019). “Effect of Waste Marble Powder and Fly Ash on The Rheological Characteristics of Cement-Based Grout”. Civil Engineering Journal, **5 (4)**, XX (Emerging SCI- WoS)

Çınar, M., Karpuzcu, M., Çanakçı, H. (2019). "The Measurement of Fresh Properties of Cement-Based Grout Containing Waste Marble Powder". Journal of the International Measurement Confederation (Measurement), XX (SCI-Exp- Under Review)

Proceedings at international and national conferences:

Çınar, M., Çelik, F., Çanakçı, H. (2015). "Effect of Rice Husk Powder Content with Different Water-Cement Ratios on Rheological Properties of Cement-Based Grouts". International Conference on Computational and Experimental Science and Engineering (ICCESEN 2015) 14-19 Oct. 2015, Antalya Türkiye

Çelik, F., **Çınar, M.**, Çanakçı, H. (2015). "Çimento Katkılı Grout'un Reolojik ve Akışkanlık Özelliklerine Pirinç Kabuğu Külünün Etkisi" 6. Geoteknik Sempozyumu 26-27 Kasım 2015, Çukurova Üniversitesi, Adana

Altunhan, İ., **Çınar, M.**, Çanakçı, H. (2015). "Investigating geotechnic properties of materials gypsum and anyhdrite that developing depending on geological structure in sivas basin hafik formation" International Conference on Computational and Experimental Science and Engineering (ICCESEN 2015) 14-19 Oct. 2015, Antalya Türkiye
