## ACKNOWLEDGEMENTS

I would like to express my gratefulness to my thesis supervisor Assist. Prof. Dr. F. Aylin Konuklar not only for her guidance but also for her patience throughout my study. She has never stopped to support me morally and I would never be able to complete my study without her knowledge and suggestions.

I am also thankful to Songül Güryel, Ahmet T. Durak and Mustafa Çoban, who are the members of Computational Chemistry Group in Informatics Institute, for their helps and suggestions for my study.

I want to express my best regards to Prof. Dr. H. Nüzhet Dalfes who showed me that there are different aspects for solutions of problems. Although a half year study with him, during my last year at undergraduate, is not actually connected with this study, I would never realized that Computational Chemistry is the right choice for me if he did not support me.

I would also like to thank to Prof. Dr. Serdar Çelebi and Assist. Prof. Dr. Lale Tükenmez Ergene for their supports during last two years in Computational Science and Engineering Programme. Their supports are very important for me to be able to understand the essentials in computational science. I also want to thank Assist. Prof. Dr. Nurcan Tüzün for her teaching of quantum chemistry which forms the basis of my study. Due to her knowledge and kindness I would be able to learn concepts about quantum chemistry which were too difficult for me to understand.

I wish to acknowledge TUBITAK for the financial support for my study. I also acknowledge the High Performance Computing Laboratory in Informatics Institute and National Center of High Performance Computing in ITU for computer facility supports.

I would like to express my deepest gratitude to my dad Şaban Gökcan, my mom Ruziye Gökcan and my sister Derya Gökcan who always support me not only financially but also morally. They always help me, thus I would never be able to come to this point if they were not with me.

Finally, I am very grateful to Çağdaş Topçu due to his efforts during my worst times. He never stopped to support me morally and always encourages me during last four years. His endless patience and encouragement always helps me to smile and solve my problems

May 2010

## A COMPUTATIONAL STUDY ON INACTIVATION MECHANISMS OF GABA – AT

### SUMMARY

$\gamma$ -aminobutyric acid (GABA) is one of the inhibitory neurotransmitter in the mammalian central nervous system which is degraded to succinic semialdehyde via transamination with R-ketoglutarate by catalysis of pyridoxal 5-phosphate (PLP)-dependent enzyme GABA aminotransferase (GABA-AT) [17]. Reduction of GABA concentration in brain causes convulsion besides several neurological diseases such as epilepsy, Parkinson's disease, Huntington's chorea, and Alzheimer's disease [14, 23]. Thus, increasing the concentration of GABA in brain will lead therapeutic applications. Due to the ineffectiveness of GABA to cross blood-brain barrier, several inactivators were reported to control the level of GABA in brain by inactivation of GABA-AT.

Silverman and co-workers have reported some fluorine containing conformationally restricted analogues of GABA as potential mechanism based inactivators [18]. One of them is 5-amino-2-fluorocyclohex-3-enecarboxylic acid. This compound could go through enzyme-catalyzed elimination that inactivates GABA-AT either by Michael addition that yields a covalently modified active site residue or an aromatization mechanism, which produces a modified coenzyme. According to the experimental results, it was observed that fluorine elimination occurs thus it is not probable to inactivate the GABA-AT via an enamine mechanism, where the fluorine elimination does not occur [18].

The ultimate aim of this study is to identify the more plausible inactivation mechanism of GABA-AT with 5-amino-2-fluorocyclohex-3-enecarboxylic acid in conjunction with experimental results. The stationary structures throughout the experimentally proposed pathways have been optimized at the B3LYP/6-31+G(d,p) level of theory. The solvent effect is also take into consideration.

## **GABA – AT İNAKTİVASYONU MEKANİZMALARI ÜZERİNE HESAPSAL BİR ÇALIŞMA**

### **ÖZET**

$\gamma$ -aminobutirik asit (GABA), memeli merkezi sinir sisteminde engelleyici sinir inhibitörlerinden olup, piridoksal 5-fosfat (PLP) bağımlı GABA aminotransferaz enziminin katalizörlüğünde R-ketoglutarat ile transaminasyonu sonucunda süksinik semialdehite degrede olur [17]. Beyindeki GABA konsantrasyonunun düşüşü konvolüsyonun yanı sıra Parkinson hastalığı, Huntington koresi ve Alzheimer gibi çeşitli nörolojik hastalıklara neden olmaktadır [14, 23]. Bu nedenden ötürü, beyindeki GABA konsantrasyonunun artırılması terapatik uygulamalar sağlayacaktır. GABA'nın kan beyin bariyerini geçememesi nedeni ile, GABA-AT inaktivasyonu aracılığıyla GABA seviyesinin kontrolüne yönelik çeşitli inaktivatörler rapor edilmiştir.

Silverman ve çalışma arkadaşları bazı florin içeren konformasyonel olarak sınırlandırılmış bazı GABA analoglarını mekanizma bazlı inaktivatörler olarak rapor etmiştir [18]. Bunlardan birisi de 5-amino-2-florosikloheks-3-enekarboksilik asittir. Bu bileşen enzim katalizli eliminasyon ile kovalent olarak modifiye edilmiş aktif bölge oluşmasını sağlayan Michael eklenmesi veya modifiye koenzim üreten aromatisasyon mejanizması aracılığı ile GABA-AT'yi inaktive etmektedir. Deneysel verilere göre, flor eliminasyonu görülmektedir, bu yüzden GABA-AT'nin flor çıkışının gerçekleşmediği enamin mekanizması ile inaktivasyonu mümkün değildir [18].

Bu çalışmanın ana amacı, deneysel sonuçlar ışığında 5-amino-2-florosikloheks-3-enekarboksilik asit ile GABA-AT inaktivasyonunda gerçekleşmesi en mümkün mekanizmanın belirlenmesidir. Deneysel olarak öne sürülmüş olunan mekanizmalarda yer alan sabit yapılar B3LYP/6-31+G(d,p) teori seviyesinde optimize edilmiştir. Ayrıca çözücü etkisi de göz önünde alınmıştır.

# **1. INTRODUCTION**

## **1.1 Enzymes**

Enzymes are specialized proteins that lower the activation energy of a reaction [1]. The catalysis performed by reducing the transition state energies and by increasing the ground state energies [2]. On the other hand, they do not change the free energy difference ( $\Delta G$ ) between the reactants and products [3].

### **1.1.1 Active Site**

In enzymes there are specific side chains that determine the catalytic activity and the specificity of that enzyme. The place that side chains form is called active site [3] which has a unique shape, such as a groove or a pocket that is specific for a particular substrate [1].

An enzyme has to be bound to its specific target which could be a small molecule or a macromolecule, to perform its task [3]. Therefore the first step in an enzyme catalyzed reaction is always the formation of the enzyme-substrate complex [1, 2]. The formation of the complex is facilitated by noncovalent interactions between the substrate and the amino acids in the active site such as ionic, ion-dipole, dipole-dipole or van der Waals interactions [2].

In an active site, there are two important regions for catalytic power, one of them binds the substrate (substrate binding region) while the other catalyzes the reaction (catalytic region). In some enzymes the substrate binding region involves the catalytic region [3].

### 1.1.2 Coenzymes

Some enzymes need another chemical component, which is called cofactor that situated in the active site and is required for the catalysis by those enzymes [2, 4].

A cofactor could be either an inorganic ion such as  $\text{Fe}^{2+}$ ,  $\text{Zn}^{2+}$ , or an organic complex which is specifically called coenzyme [4, 5]. Moreover some enzymes may need both a coenzyme and an inorganic ion [4]. Coenzymes are a kind of transition carriers that are usually derived from vitamins [4, 5].

#### 1.1.2.1 Pyridoxal Phosphate (PLP)

PLP, the phosphorylated and the oxidized form of vitamin B6 [6], is an organic cofactor in which it forms an imine with  $\epsilon$ -amino group of a lysine residue of PLP-dependent enzymes [7]. Furthermore the formation of imine could be referred as Schiff base formation [8] which takes place in lots of different chemical reactions that leads different products based on the enzyme [6]. There is a particular interest about the PLP-dependent enzymes due to the diversity of chemical reactions such as decarboxylation,  $\beta$ -elimination, aldol cleavage, transamination and transamination [6, 9, 10].

The computational studies concentrate on the formation of PLP-Schiff base [11, 12]. According to those studies, if PLP is bound to lysine residue with an imine bond and bound to the enzyme covalently, it is called an internal aldimine [6, 11]. Moreover, a new imine bond is formed due to the reaction of the substrate with the Schiff base that produces external aldimine from Michaelis complex [11, 12, 13] This reaction is called transamination or transaldimination which is symmetrical [11]. It is also known that [12, 13] in most PLP dependent enzymes the nitrogen of pyridine ring is protonated and this protonation stabilizes the interactions in enzymatic residues [14]. This stabilization is achieved due to the electron-sink effect [12, 14].

### 1.1.3 GABA and GABA-AT

GABA aminotransferase (GABA-AT, E.C. 2.6.1.19), a member of subfamily II of  $\alpha$ -family of pyridoxal 5-phosphate (PLP) dependent enzymes, is a homodimer in which all subunits contains an active site PLP that is covalently bound to Lys-329 via a Schiff base. Deduction of primary sequence of GABA-AT was established from cDNA of pig brain and peptide fragments of the enzyme from pig liver [15]. The x-ray structure of GABA-AT from pig liver was reported at 3.0-Å resolution in 1999 by Storici and co-workers that clarifies the geometry of active-site (Figure-1) [16].

$\gamma$ -aminobutyric acid (GABA) is one of the inhibitory neurotransmitters in the mammalian central nervous system which is degraded to succinic semialdehyde via GABA-AT catalyzed reaction [17]. In addition to the production of succinic semialdehyde, the neurotransmitter L-glutamate is generated via transamination of PLP, which is restored from pyridoxamine 5-phosphate (PMP), with R-ketoglutarate (R-KG) [17].

**Figure 1.1 :** GABA-AT from pig liver. **a)** X-ray diffraction. **b)** Ligand site at Chain A. **c)** Ligand site at Chain A with mesh type surface

**Figure 1.2 :** Active site of GABA – AT that involves the amino acids; Lys329, Thr353, Phe189, Arg192, Ile72 and Glu270.

Active site of GABA-AT (**Figure 1.2**) involves PHE-189 which was observed that it changed its location according to the native form [15]. ARG-192 at the active site forms a salt bridge with the carboxylate group of the inhibitor in the cases of vigabatrin and GEG [15]. Moreover, it was observed that the distance between ILE-72 and branching methyl group is short ranging [15]. In the case of 3-F-GABA as an inhibitor van der Waals interaction occurs between the GLU-270 and the carboxylic acid [18]. Furthermore, THR353 in the other monomer of the homodimer was suggested for deprotonation of the ammonium ion of 3-F-GABA [18].

## 1.2. Enzyme Inhibition and Drugs

Lots of enzymes could be inhibited by certain chemicals. Computational chemists have a particular interest in drug designing to investigate the interactions between potential drugs and biomolecules [19]. The interactions with a drug and its target, such as enzymes, could be not only the non-bonded forces but also covalent [20].

Almost all drugs have therapeutic effect by binding to the active site of an enzyme to unable the substrate to displace it and bind to the active site. As a result of this obstacle the specific biochemical pathway of the enzyme and its substrate is blocked [21].

Blocking a certain pathway by inhibition of an enzyme could be reversible or irreversible. In reversible inhibition, the chemical agent inhibits the enzyme by weak chemical bonds [22]. On the other hand, the irreversible inhibition occurs when the chemical agent inactivates the enzyme permanently [22].

The irreversible inhibition could be competitive, in which the inhibitor competes to bind the active site with the substrate of the related enzyme, and noncompetitive where the inhibitor binds a location at the enzyme other than the active site [22].

### **1.2.1 Inhibition of GABA-AT**

Reduction of GABA concentration in brain causes convulsion, besides several neurological diseases such as epilepsy, Parkinson's disease, Huntington's chorea, and Alzheimer's disease [14, 23]. Increasing the concentration of GABA in brain has an anticonvulsant effect in brain [24, 25]. Nevertheless, GABA could not cross the blood-brain barrier so controlling the GABA directly could not be performed effectively [25, 26]. Several inhibitors were used and test for controlling the level of GABA in brain by either inhibition or inactivation of GABA-AT [26, 27, 28, 29].

Diphenylhydantoin (Dilantin) was introduced as an anticonvulsant drug over 65 years ago and it is widely used, but in general it is not appropriate. As a matter of fact the ratio of epileptic patients who do not respond any anticonvulsant drug in market is about 25% of all patients. As a result, the necessity of new anticonvulsant drugs is huge [15].

One strategy to inhibit or inactivate GABA-AT is using its analog. 4-amino-5-hexynoic acid,  $\lambda$ -ethynyl GABA or GEG, is one of the earliest analog, however it did not become a clinical candidate [15].

$\lambda$ -vinyl GABA (vigabatrin) is another analog which is the most effective mechanism-based inactivator has a high potency for treatment of epilepsy, also is used in over 60 countries [15, 30, 31]. Nonetheless for effectiveness, vigabatrin should be taken daily about 0.5 g. Besides, it has some side effects, mostly a visual field defect [15]. There are three different inactivation mechanisms that have been suggested. Storici et. al. found and proposed the Michael Addition mechanism [15]. The data that have been obtained from carbon 14 labeling experiments support the Michael Addition via Enamine mechanism [15]. The last one of the suggested mechanisms is an enamine

mechanism which deprotonates the  $\lambda$ -carbon but followed a tautomerization through the vinyl double bond [30, 31].

The natural product gabaculine, which is a mechanism based inactivator of GABA-AT, is a kind of neurotoxin that was firstly isolated from *Streptomyces toyocaenis*. [11]. It was shown that gabaculine is a highly potent irreversible inactivator of GABA-AT and belongs a class of highly specific irreversible enzyme inhibitors which requires catalytic inactivation by target before inactivation step [11, 12]. Rando et. al. showed that it inactivates GABA-AT by an aromatization mechanism that modifies PLP [12]. According to the experiments, inactivation of brain GABA-AT was established by administration of gabaculine to animals and this leads an increase in level of GABA by 15-20 folds which is a proof of crossing the blood brain barrier of gabaculine [11, 13]. However, gabaculine was found toxic for theurapeutic applications due to possibility of its high reactivity with some other enzymes [12, 15].

Silverman and co-workers have reported some fluorine containing conformationally restricted analogues of GABA as potential mechanism based inactivators [14, 18]. One of them is 5-amino-2-fluorocyclohex-3-enecarboxylic acid. 5-amino-2-fluorocyclohex-3-enecarboxylic acid is a composite structure which has the form of cyclohexene analogue of (1*R*,4*S*)-(+)-4-amino-2-cyclopentene-1-carboxylic acid but with an added fluorine atom [14]. This compound could go through enzyme-catalyzed elimination that inactivates GABA – AT either by Michael addition that leads to a covalently modified active site residue (**Mechanism 1**) or an aromatization mechanism which produces a modified coenzyme (**Mechanism 2**) (**Figure 1.3**). The double bond and fluorine in the structure is important for inhibition. It was also suggested that it could go through an enamine mechanism for inactivation, just like in vigabatrin, in which fluorine elimination does not occur unlike in aromatization and Michael addition mechanisms [14]. According to the experiments, it was observed that fluorine elimination, which is suggested as in **Mechanism 1** and **Mechanism 2** (**Figure 1.3**), occurs so it is not probable to inactivate the GABA-AT via an enamine mechanism [16].

### Mechanism 1

### Mechanism 2

#### 1.2.1.1 Michael Addition

The  $\beta$  carbon of an  $\alpha$ - $\beta$  unsaturated carbonyl compounds is electrophilic due to the sharing partial positive charge of carbonyl carbon through resonance [32]. Due to this electrophilicity, a nucleophile could attack to the carbonyl group from  $\beta$  position (**Figure 1.4**) [32].

**Figure 1.4 :** Nucleophilic addition to  $\beta$  carbon. Formation of keto after protonation of enolate and tautomerization.

Michael addition is a kind of carbon-carbon and carbon-heteroatom bond forming reactions where an enolate ion is added to the double bond at an  $\alpha$ - $\beta$  unsaturated carbonyl compound [32, 33]. The Michael acceptor is the electrophile that accepts

the electron pair, while the Michael donor is the attacking nucleophile [32]. Bond formation between carbon and nitrogen via Michael addition is highly interested due to the formation of some important compounds such as  $\beta$  amino esters and derivatives [33].

Michael addition mechanisms are not only have significant roles on organic synthesis but also props in lots of enzymatic reactions [34, 35, 36]. Nucleophilic additions of DNA with prevalent Michael acceptors was studied by Pardo et. al. by examining the ammonia additions to Michael acceptors [37]. Moreover, to identify the stereochemistry of proton addition to enolate, quantum mechanical calculations were performed lots of Michael addition intermediates [38, 39]. Thomas and Kollman were also studied the Michael addition mechanism by examining the addition of sulfur nucleophiles to carbonyl compounds which are important in enzymatic processes of cysteine proteases [40].

In literature, the inactivation mechanism of GABA-AT via any of the substrate analogues has not been studied by means of computational tools. In this study 5-amino-2-fluorocyclohex-3-enecarboxylic acid is preferred in modeling the reaction mechanism. The ultimate aim of this study is to elucidate the inactivation mechanism of GABA-AT with 5-amino-2 fluorocyclohex-3-enecarboxylic acid in conjunction with experimental results. The elucidation of the inactivation reaction mechanism will make it possible to perform tailor-made synthesis for inhibitors and make great contribution to drug chemistry.

## 2. METHODOLOGY

### 2.1 The Schrödinger Equation

Erwin Schrödinger introduced a differential equation in 1926 where the wave function  $\Psi(r_1, r_2, \dots, t)$  evolves in time according to the equation

$$\hbar \frac{\partial \Psi(x,t)}{\partial t} = -\frac{\hbar^2}{2m} \frac{\partial^2 \Psi}{\partial x^2} + V(x)\Psi(x,t) \quad (2.1)$$

In this equation, which is called time dependent Schrödinger equation,  $\Psi$  is the wave function,  $\hbar$  is Planck's constant,  $m$  is mass of particle and  $V$  is the potential field. [41] The first step to solve the Schrödinger equation is expressing the wave function  $\Psi(x,t)$  as the product of two functions [42]

$$\Psi(x,t) = \psi(x)\chi(t) \quad (2.2)$$

Where the  $\psi(x)$  depends only the distance  $x$  and  $\chi(t)$  depends only the time  $t$ . If these function are substituted on the equation (2.1) and the partial derivatives are taken, it gives

$$i\hbar\psi(x) \frac{d\chi(t)}{dt} = -\frac{\hbar^2}{2m} \chi(t) \frac{d^2\psi(x)}{dx^2} + V(x)\psi(x)\chi(t) \quad (2.3)$$

If the both sides are divided by  $\psi(x)\chi(t)$  it gives

$$i\hbar \frac{1}{\chi(t)} \frac{d\chi(t)}{dt} = -\frac{\hbar^2}{2m} \frac{1}{\psi(x)} \frac{d^2\psi(x)}{dx^2} + V(x) \quad (2.4)$$

In equation (2.3) the left hand side depends only time while the right hand side depends only distance. Therefore when  $x$  changes only the right hand side changes. However the right hand side is equals to the left hand side, thus the right hand side of

the equation (2.4) must equal to a constant value. Due to the dimension of a constant are those of energy, the separation constant is determined as E, which is assumed that it is a real number [41, 42]. In consequence the equation could be separated into two parts, one time dependent and one spatial dependent. The time dependent part is shown by the equation

$$i\hbar \frac{d\chi(t)}{dt} = E\chi(t) \quad (2.5)$$

which has a solution of

$$\chi(t) = e^{-iEt/\hbar} \quad (2.6)$$

Therefore the substitution of equation (2.6) to the equation (2.2), the complete wave function has the form

$$\Psi(x,t) = e^{-iEt/\hbar} \psi(x) \quad (2.7)$$

The spatial dependent equation is given by

$$-\frac{\hbar^2}{2m} \frac{d^2\psi(x)}{dx^2} + V(x)\psi(x) = E\psi(x) \quad (2.8)$$

In this equation if the left hand side is written with the parenthesis in which whole part has the same multiplier  $\psi(x)$  it gives

$$\left[ -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + V(x) \right] \psi(x) = E \psi(x) \quad (2.9)$$

where the part in the parenthesis is referred as the Hamiltonian operator ( $\hat{H}$ ).

The Hamiltonian operator expresses the total energy in term of position and momentum [42].

$$\hat{H} = \left[ -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + V(x) \right] \quad (2.10)$$

Therefore, the time independent Schrödinger equation finally has the form of

$$\hat{H} \psi(x) = E \psi(x) \quad (2.11)$$

According to the equation (2.10) Hamiltonian is made up of both the kinetic energy and the potential energy

$$\hat{H} = T + V \quad (2.12)$$

where T is the kinetic energy operator which is related to linear momentum and V is the potential energy operator. In one dimension a particle with mass m has a kinetic energy as

$$T = - \frac{\hbar^2}{2m} \frac{d^2}{dx^2} \quad (2.13)$$

In three dimension the operator in the position representation is

$$T = - \frac{\hbar^2}{2m} \left\{ \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right\} = - \frac{\hbar^2}{2m} \nabla^2 \quad (2.14)$$

where  $\nabla^2$  (del, squared) is called the Laplacian. For an n particle system kinetic energy will have the form of

$$T = - \frac{\hbar^2}{2m} \sum_{i=1}^n \nabla_i^2 \quad (2.15)$$

Potential energy term in Hamiltonian is the Coulomb potential energy of an electron in the field of a nucleus which has an atomic number of Z

$$V = - \frac{Ze^2}{4\pi\epsilon_0 r} \quad (2.16)$$

where  $\epsilon_0$  is the permittivity constant and r is the distance from the nucleus to electron.

Therefore the potential energy term would be given

$$V = \frac{1}{4\pi\epsilon_0} \left[ - \sum_i^{\text{electrons}} \sum_j^{\text{nuclei}} \left( \frac{Z_i e^2}{\Delta r_{ij}} \right) + \sum_i^{\text{electrons}} \sum_{j<i}^{\text{electrons}} \left( \frac{e^2}{\Delta r_{ij}} \right) + \sum_i^{\text{nuclei}} \sum_{j<i}^{\text{nuclei}} \left( \frac{Z_i Z_j e^2}{\Delta R_{ij}} \right) \right] \quad (2.17)$$

where the electron-nuclear attraction is represented with the first term, electron-electron repulsion is represented with the second term and the nuclear-nuclear repulsion is represented with the last term.

## 2.2 The Born Oppenheimer Approximation

Schrödinger equation can not be solved analytically due to the number of particles in systems, even there are three particles in the simplest molecule  $H_2^+$  [41]. Born-Oppenheimer approximation takes into account the great differences in masses of electrons and nuclei to overcome the difficulty of Schrödinger equations for many particle systems. Due to the great differences between the masses of electrons and nuclei, electrons respond to the displacements of nuclei immediately. For this reason taking the position of nuclei fixed could be useful to solve Schrödinger equation [41].

The nucleus is much slower than electrons due to the differences in masses. Therefore separation of Schrödinger equation into two parts could be a good approximation, which is called Born-Oppenheimer approximation. In separated form, one part describes the electronic wave function for a fixed nuclear geometry while the other part, where wave function plays the role of potential energy, describes the nuclear wave function. According to the approximation, the electronic wave function depends only on the nuclear position not their momenta.

The total Hamiltonian is then written as

$$H_{tot} = T_n + T_c + V_{nc} + V_{ee} + V_{nn} \quad (2.18)$$

where the kinetic energy of nuclei and electrons are represented as  $T_n$  and  $T_c$  respectively, and the potential energies of nuclear-electron attraction as  $V_{nc}$ , electron-

electron repulsion as  $V_{ee}$  and nuclear-nuclear repulsion as  $V_{nn}$ . Thus, if the Hamiltonian operator is transformed to a centre of mass system it gives

$$H_{tot} = T_n + H_e \quad (2.19)$$

where  $H_e$  is the electronic Hamiltonian operator which depends only on the nuclear position and could be written as

$$H_e = T_{en} + V_{ne} + V_{ee} + V_{nn} \quad (2.20)$$

If this Hamiltonian is used in electronic Schrödinger equation

$$H_e \psi_e(R, r) = E_e(R) \psi_e(R, r) \quad (2.21)$$

$$H_n \psi_n(R) = E_{tot} \psi_n(R) \quad (2.22)$$

$$(T_n + E_e(R)) \psi_n(R) = E_{tot} \psi_n(R) \quad (2.23)$$

where  $R$  and  $n$  denote nuclear coordinates while  $r$  and  $e$  denote electronic coordinates.

The nuclear Hamiltonian  $H_n$ , describes the vibrational, rotational and translational states of nuclei. Moreover the solution of the equation (2.23) allows to lay out the molecular potential energy curve, and generally to construct potential energy surface of a polyatomic system [41].

### 2.3 The Hartree-Fock Equations

Hartree-Fock (HF) calculations are the simplest ab initio method. The problem that has been focused on is the infeasibility of the solution of Schrödinger equation for many particle systems [19].

The total wave function of an atom could be approximated as a combination of the wave function for different energy levels. Hartree's guess was depends on this fact and the method writes an approximate wave function for an atom as the product of one-electron wave function

$$\Psi_0 = \psi_0(1)\psi_0(2)\psi_0(3) \dots \psi_0(n) \quad (2.24)$$

The equation 2.24 is called the Hartree product where  $\Psi_0$  is a function of the coordinates of all electrons and  $\Psi_0(1)$  is the function of coordinate of electron 1 and so on. The one electron wavefunctions are called atomic orbital if the dealt system is an ato [19]. In the case of a molecule  $\Psi_0$  is called molecular orbital. [19] The zeroth approximation to the total wavefunction is  $\Psi_0$ .

The eigenvalue of  $\Psi_0$  could be found by the equation

$$H\Psi_0 = H \psi_0(1)\psi_0(2)\psi_0(3) \dots \psi_0(n)$$

$$H\Psi_0 = \left( \sum_{i=1}^N \epsilon_i \right) \Psi_0 \quad (2.25)$$

which proves the energy eigenvalue of a many-electron wave function is the sum of one-electron energy eigenvalue [21].

An electron on the spin orbital  $\chi_i$ , which is in the field of the nuclei and other electrons, has a Hamiltonian operator which contains three different contributions to the energy. Those contributions are the core Hamiltonian operator, Coulomb operator and the exchange operator [20]. Thus the Hamiltonian could be written as

$$H^{\text{core}}(1)\chi_i + \sum_{j \neq i}^N \zeta_j(1)\chi_i(1) - \sum_{j \neq i}^N \xi_j(1)\chi_i(1) = \sum_j \epsilon_{ij}\chi_j(1) \quad (2.26)$$

where  $H^{\text{core}}(1)$  is the core Hamiltonian,  $\zeta_j(1)$  is Coulomb and  $\xi_j(1)$  exchange operators. If the equation is simplified according to the  $\{\zeta_i(1) - \xi_i(1)\}\chi_i(1) = 0$

$$f_i\chi_i = \sum_j \epsilon_{ij}\chi_j \quad (2.27)$$

where  $f_i$  is called the Fock operator

$$f_i(1) = H^{\text{core}}(1) + \sum_{j=1}^N \{\zeta_i(1) - \xi_i(1)\} \quad (2.28)$$

while for a closed shell system it has the following form

$$f_i(1) = H^{\text{core}}(1) + \sum_{j=1}^{N/2} \{2\zeta_j(1) - \xi_j(1)\} \quad (2.29)$$

## 2.4 Slater-type Orbitals (STOs) and Gaussian-type Orbitals (GTOs)

The orbital of an atom of atomic number  $Z$  is written as

$$\phi_{nlm_l}(r, \theta, \phi) = N r^{n_{\text{eff}}-1} e^{-Z_{\text{eff}} \rho / n_{\text{eff}}} Y_{lm_l}(\theta, \phi) \quad (2.30)$$

Where  $n$ ,  $l$ ,  $m_l$  are the quantum numbers,  $N$  is the normalization constant,  $Y_{lm_l}$  is the spherical harmonic and  $\rho = r/a_0$ .  $n_{\text{eff}}$  is the effective principal quantum number which is related to the true principal quantum number  $n$  by the following map [41].

$$n \rightarrow n_{\text{eff}} : 1 \rightarrow 1 \quad 2 \rightarrow 2 \quad 3 \rightarrow 3 \quad 4 \rightarrow 3.7 \quad 5 \rightarrow 4.0 \quad 6 \rightarrow 4.2 \quad (2.31)$$

Orbitals with different values of quantum number  $n$  but same values of quantum numbers  $l$  and  $m_l$  are not orthonormal to each other. Moreover,  $s$ -orbitals with  $n > 1$  have zero amplitude at the nucleus in the case of Slater-type orbitals (STOs) [41].

Slater-type orbitals are mathematical functions to define the wave function of an electron in an atom, however they are not suitable for many electron atoms. [43] They are generally used in atomic or diatomic system calculations if high accuracy is required and also in semiempirical methods in which three and four centre integrals are not taken into account [44].

Although STOs have a number of attractive features, in *ab initio* HF theory they are limited. If the basis functions are chosen as STOs, there would be no analytical solution for the four index integral [21]. In 1950 Boys suggested an alternative to the usage of STOs that uses  $e^{-r^2}$  instead of  $e^{-r}$  where the AO-like functions have the form of a Gaussian function [45]. This AO-like functions are called Gaussian type orbitals (GTO) which are mathematical functions to define the wave function [48, 49].

The normalized GTO in atom-centered Cartesian coordinate is

$$\phi(x, y, z; \alpha, i, j, k) = \left(\frac{2\alpha}{\pi}\right)^{3/4} \left[\frac{(8\alpha)^{i+j+k} i! j! k!}{(2i)! (2j)! (2k)!}\right]^2 x^i y^j z^k e^{-\alpha(x^2+y^2+z^2)} \quad (2.32)$$

where  $\alpha$  is the exponent that controls the width of GTO and  $i, j, k$  are non-negative integers that order the nature of the orbital in a Cartesian sense.

GTO has a spherical symmetry when all of these integers are zero and it is referred as s-type GTO. If one of the indices is equal to one the function is called p-type GTO where it has an axial symmetry about a single axis. Moreover, if the sum of the indices is equal to two, it is called d-type GTO [21].

On the other hand STO calculations require less primitives than GTO basis sets to define the wave function which is also seen in Figure 2.1 [43].

**Figure 2.1 :** Approximating of several Gaussian-type orbitals with a Slater-type orbital [43]

The wave functions are defined by a finite number of functions by choosing a standard GTO basis set. Thus, the calculation approximates that an infinite number of GTO functions would be needed to define an exact wave function [43]. Although the real hydrogenic atomic orbitals have a cusp, GTOs are smooth and differentiable at the nucleus. Moreover, the GTOs is exponential in  $r^2$ , which results a rapid reduction in amplitude with distance for the GTOs, while the hydrogenic atomic orbitals are exponential in  $r$  [21].

## 2.5 Semi-Empirical Methods

In an ab initio calculation the core integral  $H_{rs}^{core}$ , density matrix elements  $P_{tu}$ , and the electronic repulsion integrals  $(rs/tu)$ ,  $(ru/ts)$  are used to calculate the Fock matrix element

$$F_{rs} = H_{rs}^{core}(1) + \sum_{t=1}^m \sum_{u=1}^m P_{tu} \left[ (rs|tu) - \frac{1}{2} (ru|ts) \right] \quad (2.33)$$

where density matrix is given as

$$P_{tu} = 2 \sum_{i=1}^{n/2} c_{ti} c_{ui} \quad (2.34)$$

and core integral is given as

$$H_{rs}^{core} = \int ds_1 \phi_r(1) \left[ -\frac{1}{2} \nabla^2 - \sum_{i=1}^k \frac{Z_i}{|r_1 - R_i|} \right] \phi_s(1) \quad (2.35)$$

An initial guess of the coefficients to calculate the density matrix values  $P_{tu}$  is necessary where it would be calculated by a simple Hückel calculation or extended Hückel calculation. To improve the energy levels and coefficients the Fock matrix of  $F_{rs}$  elements is diagonalized continually.

In an ab initio calculation much numbers of basis functions could be used. On the other hand semi-empiric methods use the basis functions which correspond to the atomic orbitals and Slater functions are used in SCF-type semi-empirical methods instead of the approximating them as sum of Gaussian functions. Moreover, semi-empirical calculations taken into account only the valance or the  $\pi$  electrons, thus the elements of core turn out an atomic nucleus plus its core electrons [19].

The cost of HF calculations is arise from the two-electron integrals which are necessary to construct the Fock matrix. Semi-empirical methods reduce the number of these integrals by taking them as zero to reduce the computational cost [44]. The integrals that are ignored are one-electron integrals involving three centers which are neglected by differential overlap [19, 44].

Furthermore, in SCF-type semi-empirical methods the overlap matrix is taken as a unit matrix ( $S=1$ ). Therefore the Roothaan-Hall equations  $FC = SCE$  are clear away

without using orthogonalizing matrix to transform this equations into standard eigenvalue form  $FC = CE$  [19].

### 2.5.1 Zero Differential Overlap (ZDO) Approximation

Zero Differential Overlap approximation is the center of semi-empirical methods. The approximation neglects all products of basis functions that depend of the same electron coordinates on different atoms [44]. The basis functions are taken to be orthonormal according to the equation (2.36) and the ZDO expands this idea to the two-electron integrals [46].

$$\int \chi_i(\mathbf{r})\chi_j(\mathbf{r})d\tau = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{otherwise} \end{cases} \quad (2.36)$$

$$\frac{e^2}{4\pi\epsilon_0} \int \dots \frac{1}{r_{12}} \chi_i(\mathbf{r}_1)\chi_j(\mathbf{r}_1)d\tau_1 \quad (2.37)$$

If  $i$  and  $j$  equals to each other ( $i=j$ ) the integral is set to zero and the two-electron integrals have the form of

$$\frac{e^2}{4\pi\epsilon_0} \int \chi_i(\mathbf{r}_1)\chi_j(\mathbf{r}_1) \frac{1}{r_{12}} \chi_k(\mathbf{r}_2)\chi_l(\mathbf{r}_2)d\tau_1d\tau_2 \quad (2.38)$$

are set to zero unless  $i=j$  and  $k=l$ .

### 2.5.2 PM3

Parametrized Model 3 was reported by Stewart at 1999 which is his third parameter set [47]. In this parameter set he adopted an NDDO functional, which is also identical to the AM1, and he used two Gaussian functions rather than four for per atom to employ a larger data set in evaluating the penalty function [21].

The Hamiltonian in PM3 contains the same elements as AM1 but the parameters in PM3 were derived using an automated parametrization procedure which was also devised by Stewart [20]. On the contrary the chemical knowledge and the intuition is the source to obtain the parameters in AM1. Thus, AM1 and PM3 have different values for some parameters. However, there are also some problems in PM3 model. One of them is the bonds where they are taken too short in the case of hydrogens and they are underestimated when they are between Si, Cl, Br, I. Additionally the amide

bond's rotational barrier is too low and in some cases it almost not exists, but it could be corrected by the usage of an empirical torsional potential.

## 2.6 Density Functional Theory (DFT)

The energy of a molecule could be determined by the molecule's electron density instead of a wave function and density functional theory is based on both the wave function and the electron density [19, 43, 48]. The function of an external potential energy which is acting on the density of the ground state energy of an inhomogeneous interacting many particle system is the main subject of density functional theory [49].

The earliest model for density functional was suggested by Thomas (1927) and Fermi (1927, 1928). In 1920 Dirac and in 1935 von Weizsacker suggested the extensions of the model [48]. However the theory was firstly proposed by Kohn and Sham in 1965, but it was started to use as a computational tool for chemical problems in 1980s [50a]. In their formulation, Kohn and Sham express the electron density as a linear combination of basis functions and from these functions a determinant is formed which is called Kohn-Sham orbitals [43]. Energy is computed by using electron density from this determinant [43]. Moreover the function of electron density depends on three variables (x, y, z), but the wave function of an n-electron molecule depends on 4n variables (three spatial coordinates and one spin coordinate) [19]. Thus the most important advantage of the DFT calculations is based on its simplicity according to the ab initio methods and the calculation time while it gives the same quality [19, 50a].

The Kohn-Sham equations are similar to the standard HF equation. However the exchange term in HF is changed to the exchange-correlation potential.

The defined electronic energy of a molecule in conjunction with Kohn-Sham studies is given by the equation

$$E_e = E_v + E_T + E_J + E_{XC} \quad (2.39)$$

The first term on the right hand side of the equation (2.39) is the potential energy term while the second term defines the kinetic energy due to the electron motion.  $E_J$  term is the Coulomb repulsion between the electrons and  $E_{XC}$  term is the exchange – correlation energy [51].

Calculating the Coulomb energy of the electrons which are on their own field is hard, but assuming that they move independently and each electron experiences the field because of all electrons [50b] it could be calculated by

$$E_J = \frac{1}{2} \iint \frac{\rho(\vec{r}_1)\rho(\vec{r}_2)}{r_{12}} d\vec{r}_1 d\vec{r}_2 \quad (2.40)$$

where the  $r_{12}$  is the distance between two electrons.

The exchange correlation functionals involves the difference between classical and quantum mechanical electron-electron repulsion. In addition to the repulsion, it also contains the difference in kinetic energy between the non-interaction system and the real system [21]. Therefore, exchange – correlation energy is defined by the following equation where  $E_{T_s}$  refers the interacting system

$$E_{XC}(\rho) = [E_T(\rho) - E_{T_s}(\rho)] + [E_{ee}(\rho) - E_J(\rho)] \quad (2.41)$$

Exchange – correlation functional is composed of two parts, the exchange part and the correlation part, hence the traditional definition of the exchange – correlational energy could be written as

$$E_{XC} = E_X + E_C \quad (2.42)$$

Due to the  $\alpha$  and  $\beta$  spin densities are contribute to give the exchange energy, exchange energy involves only the electrons of the same spin [44].

$$E_X = E_X^\alpha[\rho_\alpha] + E_X^\beta[\rho_\beta] \quad (2.43)$$

$$E_C = E_C^{\alpha\alpha}[\rho_\alpha] + E_C^{\beta\beta}[\rho_\beta] + E_C^{\alpha\beta}[\rho_\alpha, \rho_\beta] \quad (2.44)$$

where the total density is the sum of the  $\alpha$  and  $\beta$ ,  $\rho = \rho_\alpha + \rho_\beta$ , and for a closed shell singlet those are same.

Both of the exchange and correlation energies could be written in terms of energy per particle ( $\varepsilon_X$  and  $\varepsilon_C$ ) as

$$E_{XC} = \int \rho(r)\varepsilon_{XC}[\rho(r)]dr \quad (2.45)$$

$$E_{XC} = \int \rho(r)\varepsilon_X[\rho(r)]dr + \int \rho(r)\varepsilon_C[\rho(r)]dr$$

This formulation is defined as local density approximation (LDA) [52]. The exchange part of the energy density was given by Dirac exchange energy functional which is defined as

$$\varepsilon_X(\rho) = -C_X \rho(r)^{1/3} \quad (2.46)$$

$$C_X = \frac{3}{4} \left( \frac{3}{\pi} \right)^{1/3}$$

LDA indicates that the values of  $\varepsilon_{XC}$  at some position  $r$  could be calculated with  $\rho$ . Therefore, there is only one requirement for solution, a single-valued  $\rho$  at every position [21].

Constructing a gradient-corrected exchange functional to calculate accurate exchange energy was the main objective and Becke in 1988 reported a gradient corrected exchange functional as

$$E_X^{Becke}(\rho) = E_X^{LDA} - b \int \rho^{4/3} \frac{x^2}{1 + 6\beta \sinh^{-1} x} dr \quad (2.47)$$

$$x = \frac{|\nabla\rho|}{\rho^{4/3}} \quad (2.48)$$

where Becke defined  $b = 0.0042$  [53].

### 2.6.1 Hybrid Functionals

One of the key features of DFT is the incorporation of correlation effects from the beginning unlike HF theory. Furthermore, if the correlation is incorporated into the HF formalism, it causes computational overhead [20]. On the other hand, HF theory provides exact means of treating exchange contribution. Thus adding a correlation energy to the HF energy which is derived from DFT could be an attractive option [20]. However this approach did not work well.

According to the Becke's strategy the exchange correlation energy could be written as

$$E_{XC} = \int_0^1 U_{XC}^\lambda d\lambda \quad (2.49)$$

The coupling parameter  $\lambda$  takes the values from 0 to 1. If it takes the value of 0, it corresponds to a system where there is no Coulomb repulsion between the electrons. Interelectronic Coulomb repulsion is involved if the value of the parameter  $\lambda$  is chosen as 1, which is also corresponds to a real system. Solving this integral could be performed by approximation by using linear interpolation

$$E_{XC} = \frac{1}{2} (U_{XC}^0 + U_{XC}^1) \quad (2.50)$$

Becke's proposition to calculate the exchange correlation energy  $U_{XC}^1$  of a fully interacting real system is the usage of local spin-density approximation.

$$E_{XC}^1 \approx E_{XC}^{LSDA} = \int u_{XC} [\rho_\alpha(r), \rho_\beta(r)] dr \quad (2.51)$$

where  $u_{XC}$  is the exchange correlation potential density. However Becke recognised that there were some problems when the parameter  $\lambda$  is chosen 0 and according to the Becke's solution the  $U_{XC}^0$  term is removed. As a result HF/DFT exchange correlation functional could be represented by involving an LSDA gradient corrected DFT expression, which is also called hybrid DFT functional [19].

Becke in 1993 developed a hybrid functional based on exchange energy functional which is called Becke3LYP or B3LYP functional [19, 54]. This functional is written as

$$E_{XC}^{B3LYP} = (1 - a_0 - a_x)E_X^{LSDA} + a_0E_X^{HF} + a_xE_X^{Becke} + (1 - a_c)E_C^{VWN} + a_cE_C^{LYP} \quad (2.52)$$

Where  $E_X^{LSDA}$  is the pure DFT LSDA non-gradient corrected exchange functional,  $E_X^{HF}$  is the KS-orbital based HF exchange energy functional,  $E_X^{Becke}$  is the Becke's exchange functional that developed at 1988,  $E_C^{VWN}$  is Vosko, Wilk, Nusair function and  $E_C^{LYP}$  is the LYP correlational functional. The  $a_0$ ,  $a_x$  and  $a_c$  parameters (typical values are  $a_0 = 0.7$ ,  $a_x = 0.2$ ,  $a_c = 0.8$ ) are those which give the best fit of the calculated energy to molecular atomization energies [19, 44]. This functional is called gradient corrected hybrid functional.

## 2.6.2 Basis Set

Atomic orbital wave functions which are based on the solution of Schrödinger equation for hydrogen atom could be used in atomic calculations. Due to the absence of a prototype species that occupies a place which is analogous to hydrogen atom, this is not convenient for molecules [19]. Solution to this problem comes from Roothaan's and Hall's studies, which points that MOs could be represented as a linear combination of basis functions [19]. The most popular way is writing each spin orbital as a linear combination of single electron orbitals [20].

$$\begin{aligned}\psi_1 &= c_{11}\phi_1 + c_{21}\phi_2 + \dots + c_{m1}\phi_m \\ \psi_2 &= c_{12}\phi_1 + c_{22}\phi_2 + \dots + c_{m2}\phi_m \\ &\vdots \\ \psi_m &= c_{1m}\phi_1 + c_{2m}\phi_2 + \dots + c_{mm}\phi_m\end{aligned}\tag{2.53}$$

which is also written as

$$\psi_i = \sum_{s=1}^m c_{si}\phi_s \quad i = 1, 2, 3, \dots, m\tag{2.54}$$

where  $\phi_s$  represents the basis functions,  $c_{si}$  is the coefficient of the  $s^{\text{th}}$  basis function of corresponding  $i^{\text{th}}$  MO. The numbers of basis functions are represented by  $m$ .

Gaussian functions do not have a cusp at the origin and also they diminish to zero more rapidly according to the Slater functions. However unacceptable errors occur if the Slater type orbital is changed with a single Gaussian function. On the other hand, if linear combinations of Gaussian functions are used to represent the atomic orbitals, the problem would be solved [19, 20]. Therefore the linear combination has the form of

$$\phi_s = \sum_{i=1}^N d_{si}\phi_i(\alpha_{si})\tag{2.55}$$

where  $d_{is}$  represents the coefficient of the primitive Gaussian function  $\phi_i(\alpha_{is})$  and  $N$  is the number of functions.

Thus substitution of equations (2.52) and (2.53) gives

$$\psi_i = \sum_{s=1}^m c_{si} \sum_{j=1}^N d_{sj} \phi_j(\alpha_{sj}) \quad i = 1, 2, 3, \dots, m \quad (2.56)$$

## 2.7 Solvation Effect

Due to the energy interactions between the solute and the solvent, the solute properties depend on vibrational frequencies, total energy and electronic spectrum which depends on the solvent. Moreover the charge separation within the molecule could be stabilized by solvent. As a result, the solvent could change the not only the energy but also electron density [43]. Solvation effects to a structure or reaction could be visualized by adding the free energy of solvation point to point to the gas-phase PES and define another PES.

Methods to describe the effects of solvent are divided into two types. One of them describes the individual solvent molecules and the other kind treats the solvent as a continuum medium. Moreover, combinations of these kinds are also possible. These kinds could be also divided according to the usage of the classical or the quantum mechanical description. On the other hand, solvent effects could be divided into two parts as specific solvation and short-range effects.

Cavitation energy, which is one of the effects that occurs where the molecule meets the solvent shell, is the required energy to push aside the solvent molecules. Force attraction is another solvent effect which occurs due to the van der Waals, dispersion and hydrogen bonding interactions [43].

**Figure 2.2 :** A two dimensional gas-phase PES and the PES that derived from addition of solvation. Thick lines show a chemical reaction [43].

### 2.7.1 Polarized Continuum Models

Surface boundary approach is a kind of implementation of Poisson equation which was first formalized by Miertus, Scrocco and Tomassi in 1981. This formalization is called polarized continuum model (PCM) [21].

PCM manage the van der Waals surface type cavity and parametrizes the cavity/dispersion contributions based on the area of the surface.

The non-linear Schrödinger equation according to the quantum mechanical continuum models have the formulation of

$$\left(H - \frac{1}{2} V\right) \Psi = E\Psi \quad (2.57)$$

where  $V$  is the general reaction field inside the cavity which depends on wave function. If wave function is expressed as a Slater determinant the orbitals that minimizes the Schrödinger equation could be derived from [21].

$$(F_i - V) \psi_i = e_i \psi_i \quad (2.58)$$

where F is the Fock operator.

The difference between the energy in gas phase and the energy in solution gives the electrostatic component of the solvation

$$\Delta G_{ENP} = [\langle \Psi^{\text{sol}} | H | \Psi^{\text{sol}} \rangle + \langle \Psi^{\text{sol}} | G_P | \Psi^{\text{sol}} \rangle] - \langle \Psi^{\text{gas}} | H | \Psi^{\text{gas}} \rangle \quad (2.59)$$

$$\Delta G_{ENP} = \Delta E_{EN} + G_P \quad (2.60)$$

where  $\Delta E_{EN}$  is the distortion energy and EN term is associated with the electronic and nuclear components of the total energy [21].

According to PCM model cavity creation in the medium needs energy and electric charge distribution polarize the medium. Therefore the free energy of the solvation is calculated by [44]

$$\Delta G_{\text{solvation}} = \Delta G_{\text{cavity}} + \Delta G_{\text{dispersion}} \Delta G_{\text{electrostatic}} \quad (2.61)$$

Choosing the cavity as spherical is the simplest reaction field model where only the dipole moment and the net charge are considered while the cavity/dispersion effects are ignored. Thus Born model is given by [44]

$$\Delta G_{el}(q) = - \left( 1 - \frac{1}{\varepsilon} \right) \frac{q^2}{2a} \quad (2.62)$$

where q is the net charge, a is the radius of cavity,  $\varepsilon$  is the dielectric constant.

## 2.8 Population Analysis

Partitioning the wave function or the electron density into charges on the nuclei and bond orders are performed by a mathematical way which is called population analysis. The results that are obtained from population analysis are those which can not be observed by experiments. For example due to the lack of physical property, atomic charges could not be observed experimentally. On the other hand abstraction of electron density and the nuclear charges on each atom to partial charges is helpful to understand electron density distribution [43]. Thus, predicting the sites where nucleophilic or electrophilic attack could occur would be easy to predict.

### 2.8.1 Natural Bond Order (NBO) Analysis

Natural bond order analysis involves a set of analysis techniques. Natural population analysis is one of them and it is performed to obtain occupancies and charges NBO uses natural orbitals instead of molecular orbital [43]. The eigenfunctions of first order which reduces density matrix are the natural orbitals [43]. Natural orbitals could be used to derive atomic charges and molecular bonds by distribute the electrons into atomic and molecular orbitals. The shape of the atomic orbitals is defined by the one electron density matrix by performing Natural Atomic Orbital and Natural Bond Orbital analysis [44].

The electron density is calculated from the wave function by

$$|\Psi|^2 = \Psi * \Psi \quad (2.63)$$

Therefore the reduced density matrix of order  $k$ ,  $\gamma_k$ , is defined by

$$\begin{aligned} & \gamma_k(r'_1, r'_2, \dots, r'_k, r_1, r_2, \dots, r_k) \\ &= \binom{N}{k} \int \Psi^*(r_1, r_2, \dots, r_k, r_{k+1}, \dots, r_N) \Psi(r_1, r_2, \dots, r_k, r_{k+1}, \dots, r_N) dr_{k+1} \dots dr_N \end{aligned} \quad (2.64)$$

The integration of first order density matrix over the coordinate 1, yields the number of electrons. The first order density matrix could be diagonalized and Natural Orbitals and Occupation Numbers could be found [43]. The occupation number of the natural orbitals could be either 0 or 2.

The first step in NBO analysis is localization of natural atomic orbitals which are associated almost entirely with a single atom [21]. The second step involves the localization of orbitals that contains bonding/antibonding between pairs by the usage of the basis set AOs of the corresponding atoms [21, 43]. The last step in analysis is, identification of Rydberg-like orbitals and orthogonalization of orbitals with each other [21, 43]. Therefore, all of the NAOs (and also Rydberg orbitals) are described by the basis set AOs of a single atom and all of the NBOs are described by the basis set AOs of two atoms [21]. Moreover, characterization of three center bonds would be performed by decomposition into three body orbitals.

## 2.9 Potential Energy Surface (PES) and Conformational Analysis

Potential energy surface (PES) is a kind of graphical representation of the Born-Openheimer (BO) potential energy function that links key chemical concepts and basic geometrical features of any given molecule, molecular complex or a chemical reaction [50c]. The minima of a potential energy surface is the minimum energy conformations and the saddle points are the transition state. For this reason both of the minima and the saddle points are really important. The local minimum which represents the minimum energy conformation is defined by the atomic arrangements where the gradient of potential energy function vanishes [50c]. On the other hand saddle points are like the top of a mountain that would be passed from one valley to another [50c].

Small distortions not only in bond angles but also in the bond lengths cause the interconversion of the arrays of the atoms of a molecule which determines the conformations of that molecule [20, 50d]. Furthermore three dimensional structures of a molecule, define the physical, chemical and also biological properties of a molecule [50d]. In biochemical researches determining a protein structure is important, thus finding the lowest energy conformer, which is the most stable conformer, is also important. In order to find the lower energy shape of geometry a local minimum of the conformer should be found [43, 50e]. Besides the conformational differences are really important drug chemistry due to the importance of using the lowest energy conformer to prevent the deformations from the conformations [50d].

Determining the most stable conformations and transition states between the conformers could be analyzed by conformational search [50e]. The aim of a conformational analysis is identifying the dynamics of atomic motion characteristic of the conformational behavior of a molecule [50c]. Conformations of a molecule involve all of the low energy minimas on the PES. Therefore the conformational search could be referred as searching the local minimas or the low energy saddle points on the PES [50c]. Moreover the conformational analysis could be referred as the study about the conformations which affect a molecule's properties [20, 50d]. Although the earliest and the simplest conformational ideas have been performed by

Sachse and Bischoff in 1890, the modern conformational analysis has been developed by D. H. R. Barton at 1950 [20, 50d, 55].

Energy minimizations have a big role in conformational analysis. That's why having a separate algorithm is necessary to find the minimas on energy surface [20]. The energy of conformations could be calculated by ab initio, semiempirical and also MM methods. The method that is chosen to calculate the conformational energy is depends on not only the size of the molecule but also the required accuracy of the energies according to the availability of parameters [50e]. On the other hand, there could be lots of minimas on a energy surface while the Boltzmann function ( $K = \exp(\Delta G/RT)$ ) controls the distribution of the conformers of a conformational space [20, 50d]. In that case it is preferred to find all the accessible minimas [20].

## 2.10 Computational Details

The conformer analysis for the PLP – 5-amino-2 fluorocyclohex-3-enecarboxylic acid complex model structure was performed at PM3 level of theory using Spartan 04 programme [47, 56]. The first five lowest energy structures were chosen for further optimization. All of the structures; reactants, intermediates, transition states and products along the reaction path were optimized at the B3LYP/6-31+G(d,p) using Gaussian 03 programme [57]. The model compound and the intermediates formed along the reaction coordinate are changed species. Therefore, diffused functions are added to the basis set. Since the path is included proton transfers, addition of one set of p primitives to hydrogen atoms is inevitable. Once the lowest energy conformer for PLP – 5-amino-2 fluorocyclohex-3-enecarboxylic acid complex is determined, the proposed reaction mechanisms were modeled. To observe the charge distribution of the conformers and also the structures on the mechanism NBO analysis was performed. The single point energy calculations were carried out in order to determine the solvent effect with Integral Equation Formalism PCM (IEFPCM) methodology as implemented in G03 at 6-31+g(d,p) level of theory [58]. Both water ( $\epsilon=78.39$ ) and diethylether ( $\epsilon =4.335$ ) were used as a solvent in order to mimic the highly and moderately polar types of surroundings of the active site. The molecular cavity is build up with UFF radii which uses UFF force field. By choosing this model, a sphere around each solute atom with the radii scaled by a factor of 1.1 is placed where the explicit hydrogens have individual spheres.

### 3. RESULTS AND DISCUSSION

The two proposed mechanism for inactivation of GABA-AT; namely Michael addition and Aromatization mechanisms have common steps at the beginning where the PLP-substrate complex is formed, proton abstraction occurs and fluorine is eliminated. These steps are grouped under the heading of Fluorine Elimination (**Figure 3.1**, Mechanism 1). Once the fluorine is eliminated, the inactivation mechanism either follows Michael addition or Aromatization paths. Michael Addition path have several alternatives regarding the native of the assistant molecules used in the addition mechanism (**Figure 3.1**, Mechanism 2). In conjunction with the literature, two different types of aromatization mechanisms can be proposed for the carbinolamine formation step. In the first one, the proton abstraction from structure **15** occurs which is followed by the proton transfer to quinonoid (structure **17**) to form carbinolamine (**Figure 3.1**, Mechanism 3a) [13, 59]. The second one differs in the sequence of the steps where the proton abstraction from structure **15** involves the carbinolamine formation via proton transfer to structure **15** and proceeds with a proton abstraction from structure **21** (**Figure 3.1**, Mechanism 3b) [14].

### 3.1 Model Structures

In order to mimic the inactivation mechanism of GABA – AT with 5-amino-2-fluorocyclohex-3-enecarboxylic acid, model structures are used. In this study Lysine329 (Lys329), attached to PLP, has been represented as a methylamine (**Figure 3.2a**). This method of representing PLP dependent enzymes is common and widely accepted in literature [60]. Also, the phosphate group on PLP was replaced with a methyl group which is also widely used application (**Figure 3.2b**) [8,10,60]. Moreover, to model the threonine assisted stepwise Michael Addition mechanism 2-propyl alcohol is used to mimic Threonine353 (Thr353) (**Figure 3.2c**). Although being in the sequence of the other monomer, Thr353 is close to the active site based on the crystal structure (**PDB code: 1OHV**). The distance between the nitrogen at the side chain of Lys329 and the oxygen at the side chain of Thr353 is 3.791 Å (**Figure 1.2**). It was also suggested that the hydroxyl group of Thr353 could be a candidate for deprotonation of the substrate ammonium ion due to its closeness to the phosphate group of PLP [18].

**Figure 3.2 :** Three dimensional geometries of model structures. **a)** Methylamine as Lys329. **b)** 2-propyl alcohol as Thr353. **c)** PLP-methylamine complex as PLP-Lys329 complex.

### 3.2. Conformational Analysis

Conformational analysis was performed for the PLP-5-amino-2-fluorocyclohex-3-enecarboxylic acid complex (**4**) using semiempirical method PM3 implemented in the Spartan 04 programme. The first five lowest energy conformers were chosen for further optimization at high level of theory. The frequency and energy calculations

for these conformers has been performed with B3LYP/6-31+G(d,p) level. The two lowest energy conformers are depicted in **Figure 3.3**. The energy difference between the two lowest energy conformers is found to be 5.71 kcal/mol. The main structural difference between these conformers is the position of carboxyl hydrogen. The dihedral angle H20 – O19 – C17 – O18 has a value of  $0.4^\circ$  in the lowest energy conformer, where it changes to  $-176.4^\circ$  in the second lowest energy conformer.

**Figure 3.3 :** Three dimensional geometries of optimized (B3LYP/6-31+G(d,p)) geometries of PLP-5-amino-2 fluorocyclohex-3-enecarboxylic acid complex (**4**) **a)** The lowest energy conformer. **b)** The second lowest energy conformer. NBO charges are shown in parenthesis.

### 3.3 Fluorine Elimination

Fluorine elimination mechanism starts with the formation of PLP – substrate complex as Lys – 329 leaves the PLP. In this step N7 of substrate (**2**) attacks nucleophilically to the C8 of methylamine – PLP complex (**1**) (**Figure 3.4a**). The formation of a bond between N7 and C8 and a proton transfer from N7 to N25 on methylamine occurs simultaneously. In the transition state, **3TS**, the N7 – C8 – N25 is  $94.8^\circ$  and the N7 – C8 distance is  $1.503 \text{ \AA}$  (**Figure 3.4c**). In addition, the N7 – H27 and N25 – H27 distances are  $1.309 \text{ \AA}$ ,  $1.353 \text{ \AA}$  respectively. The transition state structure (**3TS**) is determined with one imaginary frequency having a value of  $-1603.92$ . The relative free energy barrier for the transition state (**3TS**) is found to be  $23.7 \text{ kcal/mol}$ . The transition state (**3TS**) was also validated with intrinsic reaction coordinate (IRC) calculations. The reverse IRC calculation produced an intermediate structure namely methylamine – PLP – substrate complex instead of the two reactants (**Figure 3.4a**). The forward IRC calculations pointed out a different PLP – substrate conformer (**Figure 3.4b**) then the conformational analysis results. However, further optimization after the removal of methylamine produced a compatible geometry.

**Figure 3.4 :** Three dimensional geometries of formation of PLP-5-amino-2-fluorocyclohex-3-enecarboxylic acid complex (structure **4**). **a)** Structure 1-2 Complex before transition state formation. **b)** Geometry optimization result from forward IRC calculation. NBO charges are shown in parenthesis.

(c)

**Figure 3.4 :** (continued) Three dimensional geometries of formation of PLP-5-amino-2-fluorocyclohex-3-enecarboxylic acid complex (structure **4**). **c)** Transition state (**3TS**) of fluorine containing PLP – 5 – amino – 2 – fluorocyclohex complex. NBO charges are shown in parenthesis.

In literature stepwise mechanism is proposed for the HF elimination step. However, calculations have revealed that a water assisted concerted mechanism (**Figure 3.5a**) is the most probable path. In transition state (**5TS**), the oxygen of water (**O30**) is found to be at a distance of 1.155 Å from H21 of C6 with an angle O30 – H21 – C6 of 159.8°. While the proton is transferred to the water, the single bond between fluorine atom and C3 breaks, and the lone pairs of fluorine atom interacts with the O30 – H31 antibonding orbital via O30 – H31 – F angle of 153.3°. The NBO second order stabilization energy is found to be 22.35 kcal/mol for this interaction. Due to the HF elimination, C3 – C4 and C5 – C6 single bonds (1.507 Å and 1.515 Å respectively) turn to double bonds (1.368 Å and 1.380 Å respectively) while the C4 – C5 double bond with the distance of 1.338 Å lengthens to single bond with the distance of 1.427 Å. Moreover, the C8 – N7 – C6 – C5 dihedral angle alters to -10.4° in structure **6** (**Figure 3.5b**), from -105.5° in structure **4**. The relative free energy barrier for this transition state (**5TS**) was calculated as 27.8 kcal/mol. The reaction is highly exergonic. The energy profile for fluorine elimination mechanism is depicted in **Figure 3.6**.

**Figure 3.6 :** Energy profile for fluorine elimination mechanism. Relative Gibbs free energies are given as kcal/mol.

### 3.4. Michael Addition

Based on the experimental findings, formation of amine bond between enolamine (**6**) and proton transfer in the presence of Lys329 via Michael addition is proposed as stepwise mechanism. [14] On the other hand, the mechanism is modeled not only as stepwise but also concerted path. The concerted mechanism is modeled using only the side chain of Lys329 which is methylamine in the model structure. The stepwise mechanism is modeled with the assistance of either water or Threonine (Thr353) which is represented as 2-propyl alcohol in the model structure. Thr353 is chosen due to its closeness to the active site although it is in the sequence of the other monomer.

In the case of concerted mechanism, the N25 of methylamine attacks nucleophilically to C3 of structure **6** while one of the protons of amino group transfers to the C4. The bond formation between the N25 and C3 was seen at a distance of 1.518 Å with an angle N25 – C3 – C4 of 96.8<sup>0</sup> (**Figure 3.7a**). The proton transfer was achieved with the N25 – H27 distance of 1.461 Å and the H27 – C4 distance of 1.344 Å while the N25 – H27 – C3 angle is 108.9<sup>0</sup>. Formation of enolimine (structure **8a**, **Figure 3.7b**) while methylamine forms a secondary amine via Michael addition with concerted mechanism has an energy barrier of 32.0 kcal/mol. The energy profile of both the concerted, water and Threonine assisted mechanisms are shown in **Figure 3.8**.

**Figure 3.7 :** Three dimensional geometries of Michael Addition mechanism via concerted mechanism. **a.** Transition state of N25-C3 bond formation and the proton transfer (**7TS**). **b.** Structure **8a**. NBO charges are shown in parenthesis.

**Figure 3.8 :** Energy profile of inhibition via Michael Addition mechanism in gas phase. — : Water assisted stepwise mechanism. - - : Thr353 assisted stepwise mechanism. - - : Concerted mechanism

In the water assisted stepwise mechanism, first the N25 of methylamine forms a single bond with C3 of structure **6**. Incorporation of water was performed with an angle C3 – N25 – O30 of  $92.9^\circ$  and the bond formation is achieved at a C3 – N25 distance of 1.505 Å. Furthermore, lone pairs of O30 interact with H27 of methylamine at a distance of 1.051 Å with an NBO second order stabilizing energy of 322.74 kcal/mol. Although the distance of O30 – H31 is 1.278 Å and H31 – C4 is 1.360 Å, the [1,3] proton transfer is not seen during this step (**9TS**, **Figure 3.9a**). The results are validated with IRC calculations. The energy barrier of this transition state which leads the formation of structure **10** (**Figure 3.9b**) was calculated as 31.1 kcal/mol.

**Figure 3.9 :** Three dimensional geometries of water assisted Michael addition mechanism. **a.** Water assisted bond formation between N25 and C3 (**9TS**). **b.** Quinonoid (structure **10a**) from geometry optimization of forward IRC calculation of **9TS**. NBO charges are shown in parenthesis.

In the second step of water assisted Michael addition mechanism, [1,3] proton transfer is achieved. The geometrical parameters for the elimination of one proton from N25 and transfer of proton from water to C4 can be seen in **Figure 3.10**. Both of the bonding and antibonding orbitals of C4 – C5 interact with the transferring proton (H31). The NBO second order stabilizing energies of the corresponding

interactions are found to be 281.25 kcal/mol and 200.24 kcal/mol respectively. Moreover the NBO second order stabilizing energy of the interaction between lone pairs of O30 and H31 is found to be 200.24 kcal/mol. The transition state (**11TS**)(**Figure 3.10a**) which has an energy barrier of 40.4 kcal/mol, results the transformation of the C4 – C5 double bond with the distance of 1.353 Å to single bond with the distance of 1.473 Å and C5 – C6 single bond with the distance of 1.439 Å to double bond with the distance of 1.362 Å. Thus the double bond between C6 – N7 (1.335 Å changes to 1.396 Å) shifts to N7 – C8 (1.363 Å changes to 1.318 Å). The transition state for this step yields structure **8b** (**Figure 3.10b**), which is also validated with geometry optimization of forward IRC result of **11TS**.

**Figure 3.10 :** Three dimensional geometries of water assisted Michael addition mechanism. **a.** Water assisted [1,3] proton transfer (**11TS**). **b.** Structure **8b** from geometry optimization of forward IRC calculation of **11TS**. NBO charges are shown in parenthesis.

The stepwise mechanism was also studied with the assistance of Thr353 (2-propyl alcohol). The first step of Thr353 assisted mechanism resembles the water assisted one. Instead of using water, N25 – C3 bond formation is achieved via the usage of 2-propyl alcohol (**12TS**, **Figure 3.11a**). The achievement of bond formation with an angle C3 – N25 – O32 of  $92.0^\circ$  and the distance C3 – N25 of 1.490 Å that yields transformations of C3 – C4 and C5 – C6 double bonds (1.368 Å and 1.380 Å respectively) to single bonds (1.509 Å and 1.439 Å respectively) and C4 – C5 single

bond with the distance of 1.426 Å to double bond with the distance of 1.352 Å. Moreover, lone pairs of O33 interacts with H27 of methylamine with an NBO second order stabilizing energy of 391.09 kcal/mol. Transition state of N25 – C3 bond formation via threonine assisted mechanism has a free energy barrier of 26.1 kcal/mol which is smaller than both the concerted and water assisted mechanisms. The result is validated with IRC calculations where the geometry optimization of forward IRC calculation of **12TS** yields structure **10** and 2-propyl alcohol (**Figure 3.11b**).

**Figure 3.11** : Three dimensional geometries of Threonine assisted Michael addition mechanism **a.** 2-propyl alcohol assisted bond formation between N25 and C3 (**12TS**). **b.** Structure **10b** from geometry optimization of forward IRC calculation of **12TS**. NBO charges are shown in parenthesis.

The last step of threonine assisted mechanism, [1, 3] proton transfer step (**13TS**, **Figure 3.12a**), is achieved with an approximation of 2-propyl alcohol where the O32 – H27, H33 – O32 and H33 – C4 distances being 1.829 Å, 1.327 Å, 1.323 Å respectively. H27 of N25 in methylamine transfers to the O32 with an angle N25 – H27 – O32 of 141.3° and the H33 of O32 transfers to C4 with an angle O32 – H33 – C4 of 152.4°. These proton transfers at the dihedral angle C3 – N25 – O32 – C4 of 10.4° results the transformation of the C4 – C5 double bond (1.358 Å) to single bond (1.481 Å) and the C5 – C6 single bond (1.432 Å) to double bond (1.359 Å).

Moreover, the bonding and antibonding orbitals of C4 – C5 interact with the transferring proton (H33) with the NBO second order stabilizing energies of 179.47 kcal/mol and 251.78 kcal/mol respectively. Also it is found that the lone pairs of O33 interacts with the H33 with an NBO second order stabilizing energy of 162.43 kcal/mol. Formation of structure **8c** (Figure 3.12b) via threonine assisted transition state requires a free energy of 37.8 kcal/mol which is smaller than the water assisted mechanism.

**Figure 3.12 :** Three dimensional geometries of threonine assisted Michael addition mechanism **a.** 2-propyl alcohol assisted [1,3] proton transfer (**13TS**). **b.** Structure **8c** from geometry optimization of forward IRC calculation of **13TS**. NBO charges are shown in parenthesis.

According to the gas phase calculations, the threonine assisted Michael addition mechanism has lower relative Gibbs free energy barriers than the water assisted mechanism. When the reaction free energy profile is analyzed in detail, it is seen that the activation energy barrier of concerted mechanism is lower than the activation energy barriers of second step of Threonine assisted mechanism. However the gained energy from the previous step is sufficient to overcome the barrier of later step. Incorporation of one water molecule does not lower the energy barrier relative to the concerted one. Moreover, water assisted mechanism proceeds to the structure **10a** with almost the same energy barrier as in the concerted mechanism which produces

the final product **8a**. On the contrary threonine assistance lowers the energy barrier by 5.1 kcal/mol according to the water assisted mechanism while it proceeds to structure **10b**. As a result of gas phase calculations, the threonine assisted mechanism is found to be the most plausible mechanism for the inactivation of GABA-AT with 5-amino-2-fluorocyclohex-3-enecarboxylic acid.

### 3.5. Aromatization Mechanisms

Aromatization mechanism may proceed via two different paths where the sequence of formation of carbinolamine is the main difference between those paths. There are two proton abstraction and one proton transfer steps in both paths. Although the first proton elimination is common, the second proton elimination and proton transfer steps are switched in the alternative path. Methylamine is used as the proton acceptor in proton elimination steps while protonated methylamine is used as proton donor in both of the paths.

Aromatization mechanisms start with the proton elimination from  $\alpha$  carbon (C2) of the substrate. In this step methylamine is used as the proton acceptor where the H22 is transferred to N25 at a C2 – H22 distance of 1.286 Å and H22 – N25 distance of 1.498 Å (**14TS, Figure 3.13a**). While the proton is transferred to N25, the double bond with a distance of 1.368 Å between C3 – C4 turns to the single bond having a value of 1.444 Å. Moreover, the double bond between C5 – C6 shifts to C6 – N7 where C5 – C6 bond length changes from 1.380 Å to 1.425 Å. This double bond shift leads to the formation of quinonoid intermediate **15 (Figure 3.13b)**. Additionally due to the charge delocalization alterations within the ring, C2 – C3 single bond (1.500 Å) to shortens to double bond (1.354 Å). Relative Gibbs free energy barrier for this transition state is found to be 8.0 kcal/mol.

**Figure 3.13 :** Three dimensional geometries of proton abstraction as the first step of Aromatization mechanisms **a.** Transition state of proton transfer to Lys329 (**14TS**). **b.** Optimized geometry of structure **15**. NBO charges are shown in parenthesis

### 3.5.1. Aromatization via Mechanism 3a

After formation of structure **15**, the next step in Mechanism 3a is the proton abstraction from the structure **15**. Methylamine is used as a proton acceptor in this step. Surprisingly, two different transition state structures is found relative to the position of methylamine. The energy profile of Aromatization path via the Mechanism 3a is shown in **Figure 3.14**.

In the first transition state structure, (**16TSa**, **Figure 3.15a**) methylamine is approaching to structure **15** with C1 – H23 and H23 – N25 distances having values 1.359 Å and 1.388 Å respectively. In addition the C1 – H23 – N25 – C29 dihedral angle and C1 – H23 – N25 angle having values  $-101.3^{\circ}$  and  $168.7^{\circ}$  respectively determines the position of methylamine in Cartesian space. The transition state is determined with one imaginary frequency having a value of -1156.97 and has a relative energy barrier of 9.4 kcal/mol. The accuracy of this step is validated with the IRC calculations where the transition state produces protonated methylamine and structure **17** with a relative energy of -87.4 kcal/mol (**Figure 3.15b**). The C1 – H23 distance is 2.908 Å, the dihedral angle C1 – H23 – N25 – C29 is  $-113.3^{\circ}$  and the angle C1 – N25 – C29 is  $121.1^{\circ}$ .

Figure 3.14 : Energy profile of Mechanism 3a in gas phase. Relative Gibbs free energies are given as kcal/mol.

**Figure 3.15 :** Proton elimination from structure **15** as the first step of Mechanism 3b. **a.** Proton transfer from structure **15** to methylamine (**16TSa**). **b.** Optimized geometry from forward IRC calculation of **16TSa**. NBO charges are shown in parenthesis

In the second transition state structure (**16TSb**, **Figure 3.16a**) of proton abstraction from structure **15**, the C1 – H23 distance is found to be 1.358 Å while the H23 – N25 distance is 1.386 Å. These distances are relative with the distances in **16TSa**. On the other hand the dihedral angle C1 – H23 – N25 – C26 is found to be 136.3° where the CH<sub>3</sub> of methylamine is placed towards the substrate ring. Moreover, the C1 – H23 – N25 angle is 169.2° which is also similar to the C1 – H23 – N25 angle in **16TSa**. The IRC calculations are also performed to validate the accuracy and it is found to be that the this transition state, with one imaginary frequency having a value of 1152.00, produces the protonated methylamine and structure **17** with a relative free energy of -87.5 kcal/mol, where it differs only by the final position of protonated methylamine in optimized geometry of the result from **16TSa** (**Figure 3.16b**). The C1 – H23 distance in structure **17** is found to be 2.908 Å just like in optimized structure of forward IRC calculation of **16TSa**. On the other hand, the dihedral angle C1 – H23 – N25 – C29 is found to be 139.0° and the C1 – N25 – C29 is 141.8° which are also different from optimized structure of forward IRC result of **16TSa**. The relative Gibbs free energy barrier is found to be 8.9 kcal/mol for this transition state and it is 0.5 kcal/mol lower than the barrier of **16TSa** where the optimized geometries from IRC results have the same energies.

**Figure 3.16 :** Proton elimination from structure **15** as the first step of Mechanism 3b. **a.** Proton transfer from structure **15** to methylamine (16TSb). **b.** Optimized geometry from forward IRC calculation of 16TSb. NBO charges are shown in parenthesis

The proton transfer from protonated methylamine to C8 is achieved in such a way that the distance between N12 and H is 1.282 Å where it is 1.472 Å between C8 and H. The C8 – H – N25 angle is 163.7° where the C9 – C8 – H – N25 dihedral angle is 144.1° and the N7 – C8 – H – N25 dihedral angle is 17.0°. The transition state (**18TS**, **Figure 3.17a**) leads the change of double bond with the distance of 1.370 Å between C8 – C9 to single bond while the distance turns to 1.517 Å. Proton transfer leads aromatic compound **19** (**Figure 3.17b**) where the uncharged N12 gains a positive charge. The transition state (**18TS**) is determined with one imaginary frequency having a value of -1143.34 and has a free energy barrier of 5.8 kcal/mol when the structure **17** is taken as optimized geometry of forward IRC result of 16TSa and 5.9 kcal/mol when the structure 17 is taken as optimized geometry of forward IRC result of 16TSb.

**Figure 3.17 :** Proton transfer to structure **17**. **a)** The last step of Mechanism 3a, (**18TS**). **b)** The final product (**19**). NBO charges are shown in parenthesis.

### 3.5.1. Aromatization via Mechanism 3b

After proton abstraction from structure **6** in Mechanism 3b, the next step is the proton transfer to C8. The proton donor for this step is chosen as protonated methylamine to represent the positively charged lysine. In the transition structure **20TS**, N25 – H and C8 – H distances are 1.278 Å and 1.493 Å respectively. The N25 – H – C8 and C9 – C8 – N7 angles are 176.6 and 118.0° respectively. The transition state (**20TS**, **Figure 3.18a**) yields the structure **21** (**Figure 3.18b**). The double bond between C8 – C9 turns to single bond while the distance changes from 1.393 Å to 1.524 Å. Moreover, the C9 – C8 – N7 – C6 dihedral angle is 180.0° in structure **15** while it changes to 144.6° in structure **21**. The relative energy barrier for this transition state is calculated as 53.1 kcal/mol. The energy profile for aromatization via Mechanism 3b is given in **Figure 19**.

**Figure 3.18 :** Proton transfer step of Mechanism 3a and the associated product.  
**a.** Proton transfer from protonated Lys329 to structure **15** (**20TS**).  
**b.** Optimized geometry of structure **21**. NBO charges are shown in parenthesis.

The next step in Mechanism 3b is the proton transfer from structure 21. However, no transition structure can be modeled up to now. All of the attempts failed where the approximations of methylamine are relative to the **14TS** and especially in **16TS**. The reason for inability to find a transition state structure could be the steric effects due to the geometry.

As a result of the gas phase calculations for aromatization mechanisms, the Mechanism 3a has lower energy barrier than Mechanism 3b at their second steps (**16TS** and **20TS**). The Gibbs free energy barrier gap between **16TS** and the **20TS** is 44.2 kcal/mol. Moreover, the relative Gibbs free energy of **16TS** (-77.3 kcal/mol) is lower than the relative Gibbs free energy of **20TS** (-33.1 kcal/mol). Although there is no comparable result for **22TS** with **18TS**, it could be said that aromatization mechanism via Mechanism 3a is more preferable than the Mechanism 3b.

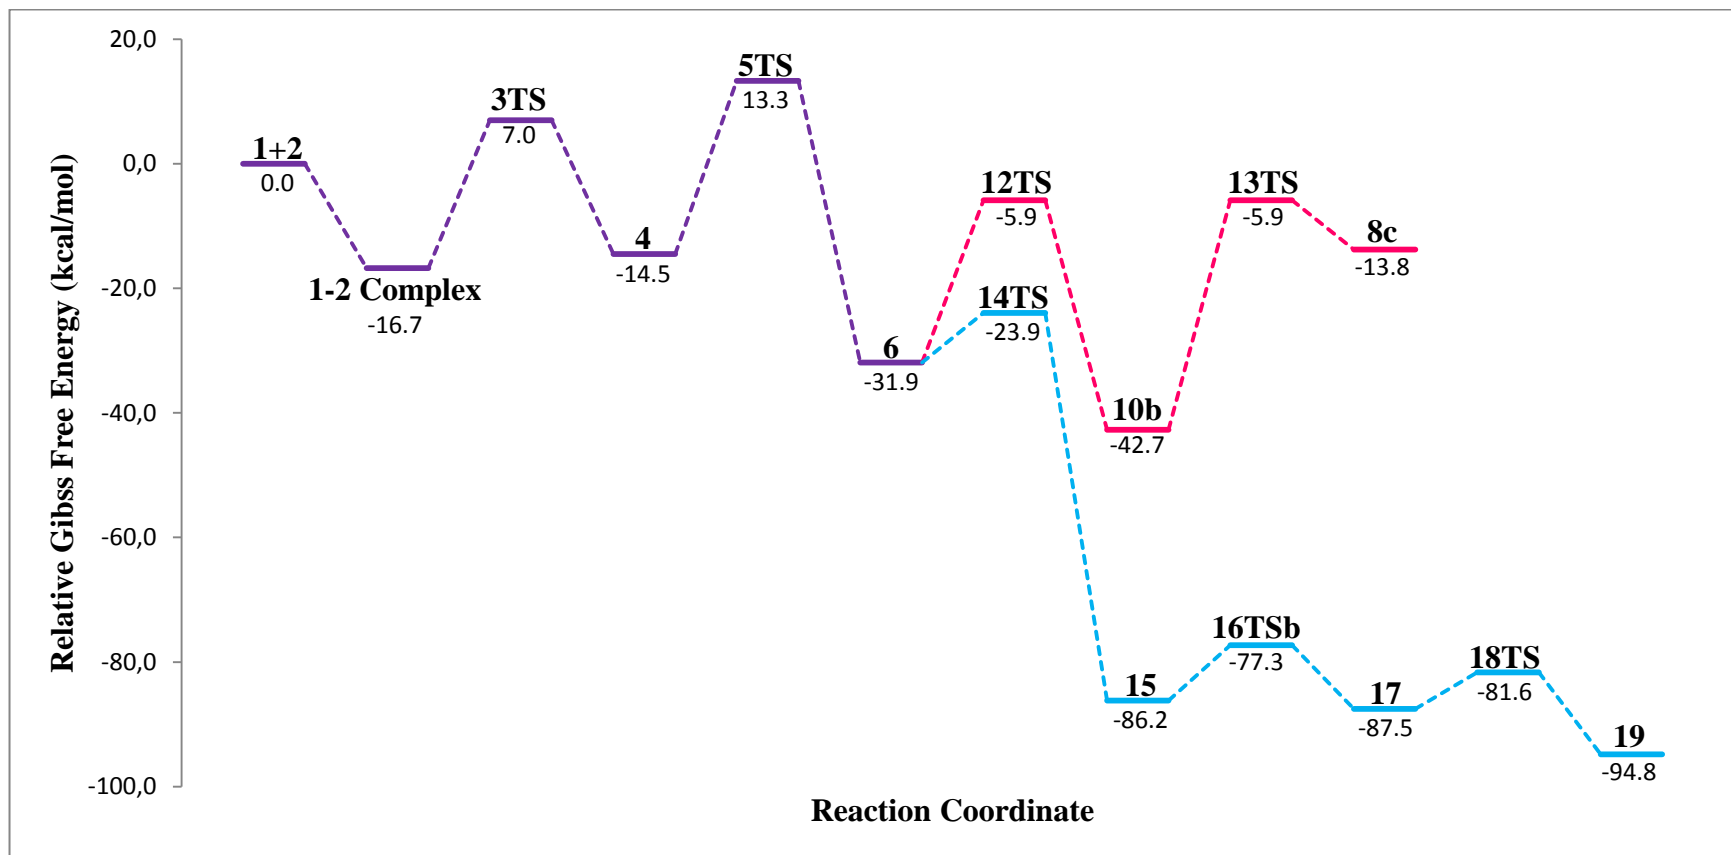

**Figure 3.19** : Energy profile of Mechanism 3b in gas phase. Relative Gibbs free energies are given as kcal/mol.

Furthermore, the relative Gibbs free energy of the final product of Mechanism 3a (-94.8 kcal/mol) is smaller than the relative Gibbs free energy of the final product of threonine assisted Michael addition mechanism (-13.8 kcal/mol) which is the more preferable Michael addition path. Thus the final product of Mechanism 3a (**19**) is more stable than the structure **8c**. Additionally, the relative Gibbs free energy of rate determining step of Mechanism 3a (**14TS**, -23.9kcal/mol) is lower than the relative Gibbs free energy of rate determining step of threonine assisted Michael addition mechanism (**13TS**, -5.9 kcal/mol). Moreover the activation free energy barrier for **13TS** is bigger than the **14TS** and also bigger than the remaining steps of Mechanism 3a (**16TS** and **18TS**). As a result, Mechanism 3a is found to be more plausible inactivation mechanism of GABA-AT with 5-amino-2-fluorocyclohex-3-enecarboxylic acid.

In conclusion, the rate determining step for threonine assisted Michael addition mechanism is **13TS** and it is **14TS** in Mechanism 3a. On the other hand, it is found to be that the rate determining step for overall reaction coordinate is the fluorine elimination step (**5TS**) which has a relative Gibbs free energy of 13.3 kcal/mol (**Figure 3.20**). Threonine assisted Michael addition have less free Gibbs energy barriers relative to the water assisted and concerted ones. However, inactivation via Aromatization mechanism is found to be the more plausible path while the Mechanism 3a is the most preferable path due to the reasons that are mentioned above.

### 3.6 Solvent Effect

The effect of the solvent on modeled mechanisms was studied with IEFPCM method. Two types of solvent environments was chosen; water ( $\epsilon=78.39$ ) and diethylether ( $\epsilon=4.335$ ). It was found that almost all the barriers are fall off while relative free energies that define the potential surface increased. In the case of the diethylether, the relative energies are smaller than the case of the water as the solvent. Moreover, the smaller energy barriers are seen when the diethylether is chosen as the solvent type.

**Figure 3.20 :** Energy profile of inactivation of GABA-AT via threonine assisted Michael addition mechanism and aromatization mechanism via Mechanism 3a. Fluorine elimination is shown in **purple**, threonine assisted Michael addition is shown in **pink** and Mechanism 3a shown in **blue**. Relative Gibbs free energies are given in kcal/mol.

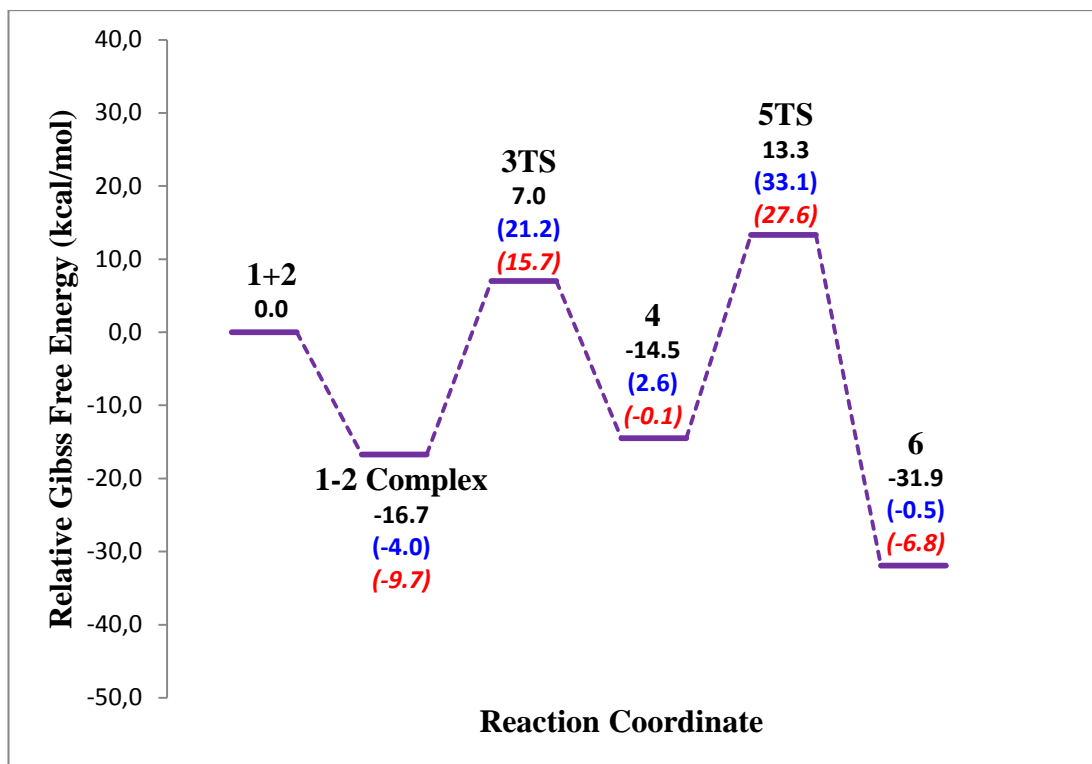

### 3.6.1. Solvent Effect on Fluorine Elimination

The first step in fluorine elimination mechanism is the formation of substrate – PLP complex. The methylamine – PLP – substrate complex has a relative energy as -16.7 kcal/mol in the gas phase while it increases to -9.7 kcal/mol in diethylether and -4.0 in the water cases. Moreover the relative energy for transition state structure is increased to 15.7 kcal/mol in the diethylether and 21.2 kcal/mol in the water from -16.7 kcal/mol. The required energy barrier for this step is increased to 25.2 kcal/mol when the solvent is water. On the other hand, the required energy is increased to 25.4 kcal/mol in the diethylether case. Therefore, the energy barrier increases for water and diethylether are 1.5 kcal/mol and 1.7 kcal/mol respectively. Thus, it could be said that the increases in the energy barrier are almost same. The energy profile for both the gas phase, water as the solvent and diethylether as the solvent is given in **Figure 3.21**.

The step where the fluorine is eliminated via water assistance has an energy barrier of 27.8 kcal/mol in the gas phase. The energy increase is also seen in this step where the barriers are increased to 30.5 kcal/mol for water and 27.7 kcal/mol for diethylether. There is an energy gap as 2.8 kcal/mol between the water and the diethylether cases where the diethylether as the solvent gives the smaller barrier.,

### 3.6.2. Solvent Effect on Michael Addition Mechanism

There are three types of Michael Addition mechanisms which are investigated. The first one is the concerted Michael addition which is calculated with methylamine. The second one is the water assisted Michael Addition where the water is used to assist bond formation between methylamine and structure **6**, and [1,3] proton transfer. The last one is the Threonine assisted Michael Addition which resembles the water assisted one.

**Figure 3.21 :** Solvent effect on Fluorine elimination. Gas phase energies are written in **black**, the energies when the solvent is water is written in **blue** and the energies when the solvent is diethylether is written in **red**. All of the relative Gibbs free energies are given in kcal/mol.

The increase in relative free energy barriers along the reaction coordinate of the concerted mechanism is 3 kcal/mol. The barrier for this step (**7TS**) in gas phase is 32.0 kcal/mol while it increases to 35.4 kcal/mol in water and 34.7 kcal/mol in diethylether. The energy gap between water and the diethylether cases is 0.7 kcal/mol thus the barrier increments are almost the same. The energy profile for both of the cases is shown in **Figure 3.22**.

In water assisted Michael addition the first step has an energy barrier of 31.1 kcal/mol in gas phase. In this step, the water is selected as the solvent, the barrier decreases to 26.0 kcal/mol where it decreases to 23.6 kcal/mol when the diethylether is used as solvent. The energy gap between the barriers of the solvents is 2.4 kcal/mol where the diethylether gives the better result.

The second step (**11TS**) in water assisted Michael Addition Mechanism is the [1,3] proton transfer. This step has an energy barrier as 40.4 kcal/mol in the gas phase. However, the energy barrier for this step decreases when the water is used as solvent. The required relative free energy for this step (**11TS**) is found to be 35.1 kcal/mol with a decrease of 5.3 kcal/mol and it is compatible with the activation free energy barrier of concerted one (**7TS**). Additionally, diethylether is also decreases the energy barrier to 36.2 kcal/mol. Those results indicate that the water assisted mechanism in the presence of water as the solvent for this step (**11TS**) have almost the same energy relative to the concerted manner. Thus, the relative free energy gain from the previous step (35.1 kcal/mol and 36.6 kcal/mol for water and diethylether as solvents respectively), the relative free energy of the **11TS** (25.4 kcal/mol for water as solvent and 16.4 kcal/mol for diethylether as solvent) and also having lower relative energies of the product compared to the concerted mechanism makes water assisted mechanism more preferable than the concerted one.

The threonine assisted Michael addition mechanism starts with bond formation between methylamine and PLP – substrate complex (**12TS**) as in the water assisted manner (**9TS**). It is mentioned before that the relative energy for this step is smaller than both of the water assisted and the concerted Michael Addition mechanisms in gas phase. The usage of water as the solvent does not make too much difference in energy barrier where it is 25.9 kcal/mol and which is almost same as in the gas phase. However, it was found that the usage of diethylether as the solvent decreases the Gibbs free energy barrier by 2.9 kcal/mol where the required energy is 23.1 kcal/mol. This energy barrier is similar to the water assisted manner.

The required energy for the last step of the threonine assisted mechanism (**13TS**) is 26.0 kcal/mol in gas phase calculations. However the Gibbs free energy barrier increases to 48.1 kcal/mol when the water is used as the solvent. Although the required energy of the threonine assisted manner is smaller than the water assisted manner in gas phase, the presence of the water as the solvent makes threonine assisted mechanism less preferable than the water assisted manner. On the other hand, the usage of diethylether decreases required energy where the decrement is 3.4 kcal/mol. Despite the fact that the required energy is smaller than the water when

diethylether is the solvent, the final product of threonine is less stable than the water assisted mechanisms where the transition structures have almost the same energy.

As a result, the usage of water as the solvent lowers the required energy for the first step in water assisted mechanism while the energy barrier for threonine assisted mechanism increases. Although the water assisted Michael Addition at the step of **9TS** has almost same energy barrier relative to the concerted manner in the gas phase, it is found that in the case of the water as the solvent, it become almost same as the concerted mechanism. When the diethylether is used as the solvent at step where the [1,3] proton transfer occurs, the required energy for threonine assisted mechanism is decreased while it increases for water assisted mechanism. In other words, threonine assisted manner has smaller energy barrier than water assisted one both in the gas phase and in diethylether. However, it is found that the water assisted Michael Addition is much more exothermic than the threonine assisted one. Due to the same relative energies of transition structures, the energy gain from the last step of the water assisted manner is much bigger than the threonine assisted manner. Thus, according to the SCRF calculations, the most preferable mechanism is not the threonine assisted mechanism, it is water assisted Michael Addition.

### **3.6.3. Solvent Effect on Aromatization Mechanisms**

The first step in both of the aromatization mechanisms is the proton transfer to methylamine and formation of structure 15 and protonated methylamine. In this step the required energy barrier in gas phase is 8.0 kcal/mol as mentioned above. It was found that the usage of solvent increases the required Gibbs free energy. When the water is used as solvent, the relative Gibbs free energy barrier increases to 16.2 kcal/mol. On the other hand, when the diethylether is the solvent, the relative energy of the transition structure (**14TS**) increases to 8.8 kcal/mol. In spite of the differences in relative energies of the transition structure, the required energies are not that much different. The required energy in the solvents as water and diethylether are 16.8 kcal/mol and 15.6 kcal/mol respectively.

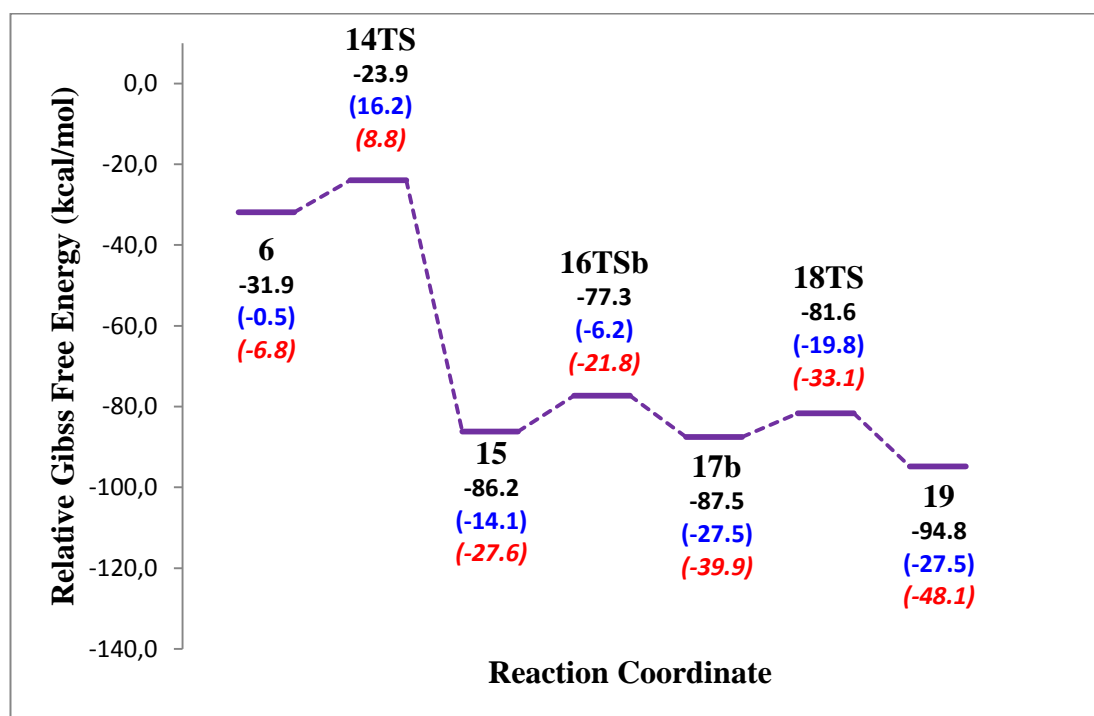

**Figure 3.22 :** Solvent effect on Michael Addition mechanism. — : Water assisted stepwise mechanism. — : Thr353 assisted stepwise mechanism. — : Concerted mechanism. Gas phase energies are written in **black**, the energies when the solvent is water is written in **blue** and the energies when the solvent is diethylether is written in **red**. All of the relative Gibbs free energies are given in kcal/mol.

### 3.6.3.1 Mechanism 3a

After proton abstraction from structure **6**, the second step in the Mechanism 3a is proton elimination from structure **15** (**16TSb**). The required energy for this step is 8.9 kcal/mol in the gas phase. When the calculations are performed in water, the energy barrier decreases to 8.0 kcal/mol, but it is only 0.9 kcal/mol lower than the gas phase (8.4 kcal/mol for **16TSa**). On the contrary, when the diethylether is used as the solvent, the required energy for this step decreases to 5.8 kcal/mol where the decrement is 3.1 kcal/mol (6.1 kcal/mol for **16TSa**). The required energy differences according to the solvent types and gas phase could be seen in energy profile for both of the situations of aromatization via Mechanism 3a (**Figure 3.23**).

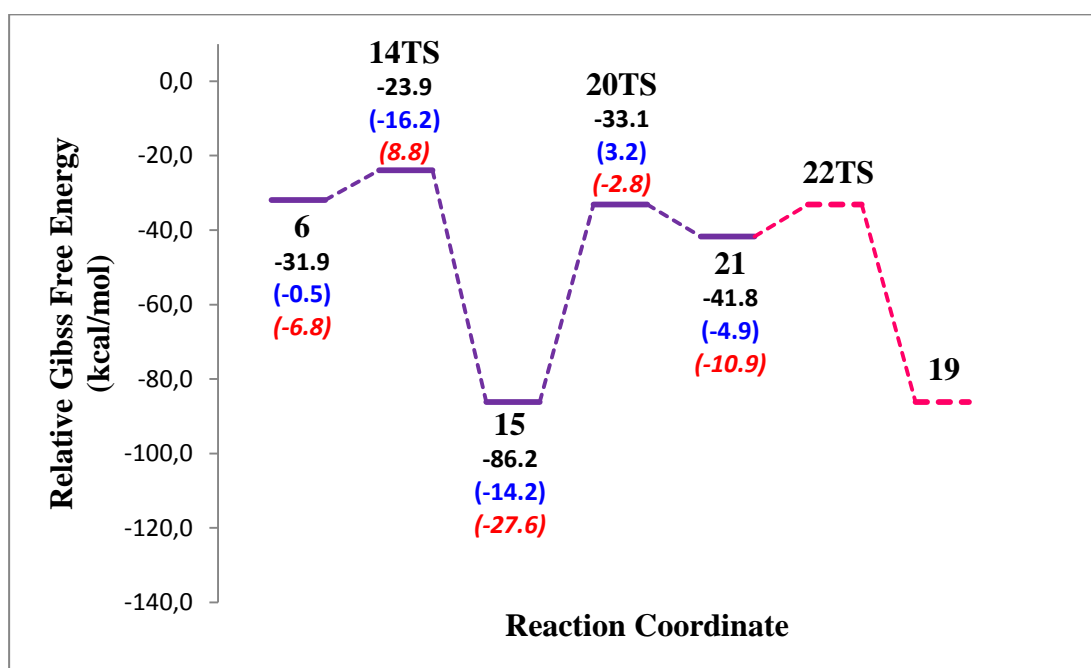

**Figure 3.23** : Solvent effect on Aromatization via Mechanism 3a. Gas phase energies are written in **black**, the energies when the solvent is water is written in **blue** and the energies when the solvent is diethylether is written in **red**. All of the relative Gibbs free energies are given in kcal/mol.

The last step in Mechanism 3a is the proton transfer to structure **17** where the protonated methylamine is chosen as the proton donor. In the gas phase, the required energy for this step is 5.9 kcal/mol. This energy barrier increases to 7.6 kcal/mol with

an increment of 1.7 kcal/mol when the water is used as the solvent. In the case of the diethylether, the increment is 0.9 kcal/mol where the barrier is 6.8 kcal/mol. Hence, the usage of diethylether gives better result than the water as the solvent.

### 3.6.3.2. Mechanism 3b

The second step in Mechanism 3b is the proton transfer to structure **15** where the proton donor is chosen as the protonated methylamine (**20TS**). This step requires an energy of 53.1 kcal/mol in the gas phase. The usage of solvent sharply decreases the energy barrier. The required free Gibbs energies for **20TS** in water and diethylether are 17.3 kcal/mol and the 24.9 kcal/mol respectively. The largest improvement is seen in the usage of water as the solvent for this step. The decrement in the water as the solvent is 36.4 kcal/mol while it is 28.2 kcal/mol when the diethylether is the solvent. The energy profile that involves both of the solvents and the gas phase is depicted in **Figure 3.24**.

**Figure 3.24** : Solvent effect on Aromatization via Mechanism 3b. Gas phase energies are written in **black**, the energies when the solvent is water is written in **blue** and the energies when the solvent is diethylether is written in **red**. All of the relative Gibbs free energies are given in kcal/mol.

In conclusion, according to the gas phase calculations and the calculations to investigate effect of solvent, Mechanism 3a have the lowest energy barriers. Also the relative energies of transition structures in Mechanism 3a have the lowest values relative to the whole mechanisms according to the SCRF calculations. Moreover, the final product of Mechanism 3a has a relative free energy of -27.5 kcal/mol in water and -48.12 kcal/mol in diethylether which are smaller than all of the Michael Addition mechanisms. As a result of having the lowest energy barriers and relative energies, the most preferable mechanism for inactivation of GABA-AT with -amino-2 fluorocyclohex-3-enecarboxylic acid is found to be the aromatization via Mechanism 3a which is also the more plausible one in gas phase calculations.

#### 4. CONCLUSION

Inactivation mechanism occurs either via Michael Addition or Aromatization mechanism. Both mechanisms have common step at the beginning where fluorine is eliminated. Although it has been suggested that the fluorine elimination occurs via stepwise mechanism, it has been found that fluorine is eliminated via concerted mechanism in the presence of water assistance. The rate determining step has been found to be the fluorine elimination with a relative free energy value of 13.3 kcal/mol.

It has been proposed that the Michael Addition proceeds via concerted or stepwise mechanisms. However, it has been found that assistance of water or threonine leads the formation of stepwise mechanism. According to gas phase calculations, threonine assistance decreases relative free energies. It is also noticeable that the second step of threonine assisted mechanism has a higher free energy barrier than concerted step, but the energy gain from previous step facilitates to overcome this free energy barrier. Based on the gas phase calculations, it can be deduced that stepwise threonine assisted Michael Addition is more prone to occur.

In aromatization mechanism two paths, namely Mechanism 3a and Mechanism 3b, were proposed. The only difference between two paths is the order of proton transfer. Unfortunately, one of the transition states of the Mechanism 3b cannot be modeled. It is noteworthy to state that, when the second steps of two paths are compared both the activation energy barriers and relative free energies indicate that path 3a is more preferred relative to the path 3b.

The product of aromatization mechanism is more stable than the one obtained from Michael Addition. Having the information provided from gas phase calculations, it can be deduced that Aromatization is the preferred mechanism. Our results are in harmony both with the calculations on the PLP – dependent enzymes and experimental evidence.

The solvent effect has been also taken into consideration. The Michael Addition mechanisms have been severely affected by the addition of water where the water assisted mechanism became more plausible than threonine assisted one. However, this does not affect the overall conclusion. Both gas phase and solvent calculations pointed out that the inactivation of GABA – AT with 5-amino-2 fluorocyclohex-3-enecarboxylic acid occurs via Aromatization mechanism.

## **APPENDICES**

**Appendix A :** Gibbs free energies and relative Gibbs free energies of molecules in gas phase. PCM energies and relative PCM energies of molecules in water as the solvent and diethylether as the solvent.

**Appendix B :** Gaussian03 input file samples.

## APPENDIX A

### Gas Phase Gibbs Free Energies

## CIRRICULUM VITAE

- Full name** : Hatice GÖKCAN
- Place of birth** : Etimesgut
- Date of birth** : 14.08.1984
- High school** : 19 Mayıs Anatolian High School, 19 Mayıs, Samsun
- University** : **B. Sc.** : (2002 – 2007) ITU Molecular Biology and Genetics  
: **M. Sc.** : (20 08 - 2010) ITU Informatic Institute,  
Computational Science and Engineering
- Publications** : **Gökcan, H.**, Konuklar, F. A., 2009, Inactivation Mechanism of GABA-AT by 5-amino-2 fluorocyclohex-3-enecarboxylic acid: A Computational Study, *DFT09 International Conference on the Applications of Density Functional Theory in Chemistry and Physics*, August 31 – September 4, Lyon, France  
**Gökcan, H.**, Konuklar, F. A., 2010, Computational Study on Two Competing Mechanisms of Inactivation of GABA-AT, *7th Congress on Electronic Structure: Principles and Applications (ESPA)*, June 29 – July 2, Oviedo, Spain
