DOUBLE DIFFERENTIAL CROSS SECTION OF THE
SECONDARY PARTICLES (n, p, α) AFTER SPALLATION
FOR ${}_{90}\text{Th}^{232}$ AND ${}_{5}\text{B}^{10}$ ELEMENTS

MASTER'S THESIS

Majd Hamad SMAIL

Department Institute : PHYSICS

This thesis was unanimously approved by the following jury on 07.05.2018

Associate Prof. Dr.
Bayram GÜNDÜZ
Member

Prof. Dr.
İskender DEMİRKOL
President of the Jury

Assistant Prof.Dr.
Kamuran DİLSİZ
Member

I confirm the results above

Associate Professor Dr. ZaferŞİAR
Director of the Institute

ACKNOWLEDGEMENTS

My deepest gratitude goes to the Most Merciful Allah S.W.T., who granted me the opportunity to pursue my MSc. degree study in Turkey. However, this project would have been impossible without the continuous support and supervision of my supervisor, Professor Dr. Iskender Demirkol. All steps taken on the way to finishing this thesis were under his direct guidance. Beginning from the very idea of the thesis until aiding this research through his grant, he acted not only as a supervisor, but also as a brother. I am deeply indebted to his. Also, I cannot forget the helpful comments from Associate Professor Dr. Nezir Yildirim, Professor Dr. Murat Soylu and Associate Professor Dr. Ferdi Akman. I am also thankful to all the laboratory assistants, and to the staff at Bingol University, who endured with me with great patience in all my laboratory tasks.

I would also want to express my full gratitude to my beloved wife who endured difficult days in Turkey, helping me with all that she got during my study. Similarly, many thanks go to my beloved brothers and sisters who supported me with prayers and endure the pain of being away for few years. My friends, who helped me with all what they got, I will never forget. Finally, I pray to Allah to give me a chance to use my experience for the reconstruction of my country.

${}_{90}\text{Th}^{232}$ VE ${}_5\text{B}^{10}$ ELEMANTLARI İÇİN SPALLASYON SONRASI OLUŞAN İKİNCİL PARÇACIKLARIN (n, p, α) ÇİFT DİFERANSİYEL TESİR KESİTİ

ÖZET

Bu çalışmada $p + {}_{90}\text{Th}^{232}$ ve $p + {}_5\text{B}^{10}$ spallasyon reaksiyonu sonrası oluşan ikincil parçacıkların (n,p, α) çift diferansiyel tesir kesiti hesaplamaları elde edilmiştir. Hesaplamalar kaskat eksiton modeli kullanan CEM03 bilgisayar programı kullanılarak yapılmıştır. Protan ışını spallasyonu oluşturan mermi olarak kullanıldı ve enerjisi 20 ile 660 Mev aralığında seçilmiştir. Hesaplamalarda spallasyon sonrası oluşan toplam, kaskad, bileşiköncesi ve buharlaşma safhaları için n,p ve α 'nın çift diferansiyel tesir kesitleri de ayrıca elde edilmiştir. Elde edilen sonuçlar Nükleer Enerji Ajansı (NEA) dan elde edilen deneysel datalar ile karşılaştırılmıştır.

Anahtar Kelimeler: Çift diferansiyel, spallasyon, enerji, nükleer reaksiyon, hızlandırıcı, tesir kesiti ve CEM03 kodu.

DOUBLE DIFFERENTIAL CROSS SECTION OF THE SECONDARY PARTICLES (n, p, α) OCCURED AFTER SPALLATION FOR ${}_{90}\text{Th}^{232}$ AND ${}_{5}\text{B}^{10}$ ELEMENTS

ABSTRACT

In this study, double differential cross section of the secondary particles (n, p, α) occurring after spallation in the reactions $p + {}_{90}\text{Th}^{232}$ and $p + {}_{5}\text{B}^{10}$ were obtained. Calculations were made by Cascade Exciton Model (CEM03) computer program. The proton beam was used as the projectile forming, the spallation and the energy was selected in the range of 20 to 660 MeV. In the calculations, double differential cross sections of n, p and α were also obtained for the total, cascade, pre-compound and evaporation phases after spallation. The results are compared with the experimental data obtained from the Nuclear Energy Agency (NEA).

Keywords: Doubledifferential, spallation, energy, nuclear reaction, accelerator, cross section and CEM03 code.

1. INTRODUCTION

The spallation reactions are one branch of the nuclear reactions. In general, they are defined as the collision or interaction of two particles, more often than the collision of a nucleon with nucleus. The first particle is a projectile which is a fast bombarding particle and the second particle is a stationary called the target (Meyerhof 1967). The bombardment energy is more or less between (100 – 3000) MeV. Through this interaction many nucleons are emitted such as (n, α , p) emitted and the remaining nucleus be able to be very various for the target nucleus also near the beginning studies of spallation reactions took place in 1947 at the University of California in the Berkeley cyclotron (Brobeck et al. 1947).

Recently, spallation reactions have attracted significant attention due to their significance in technical applications. For instance, they can be utilized for the production of neutrons in a spallation neutron source, and they can perform as an intense neutron source in accelerator-driven subcritical reactors (ADS-R), capable of incendiary nuclear waste and of producing energy. It is suggested that in the following production radioactive beam facilities, projectile disintegration at relativistic energies will be one of the main producing modes. The production of remaining output nuclei in proton collisions with an intense target nucleus is due to the intranuclear process of spallation, fragmentation, fission, and the total evaporation of light nuclei and nucleons (Demirkol 2006).

A large quantity of spallation neutrons or alpha is emitted from a target nucleus by proton bombarding together with incident intermediate energy around (MeV or GeV). Recently, the studies on the spallation reaction have been made for this application as spallation neutron sources and accelerator driven transmutation systems. Nuclear data are very essential for these objectives in the energy region nearly up to a few GeV. Several spallation sources for solid state and material physics are under structure or study many countries, for instance spallation neutron source.

Spallation neutron sources also be utilized in Accelerator Driven Systems to drive sub-critical reactors, in which long lived nuclear waste could be burned (Bowman et al. 1992), (Takizuka 1994) and (Rubbia et al. 1995). All of that systems have in mutual a spallation target made of a heavy element, either solid (Th) or liquid (Hg) (Armstrong and Chandler 1977). Nuclear power is a type of capable and cleanly energy.

The Accelerator Driven Nuclear Energy System (ADS) is a credible option to dissolve the efficient utilize of the resources and the eventual processing of long-lived nuclear waste, and will become the transmission between current commercial nuclear power system and fusion energy system. The capability and fuel of nuclear waste transmutation deepened using of accelerator driven system broadly depend on the energy and number distribution of outer neutron sources maintain the subcritical reactor of accelerator driven system and are produced from the height energy proton bombardment of heavy nuclei. For the whole ADS system in the high energy proton nuclear reactions depended on the basis of micro data. Therefore studying theory and micro data is very importance for high energy protons and heavy metals reactions (Kirkby and Link 1966). As in traditional reactor physics, the basic of nuclear reaction information is preliminary point of any gross-scale modeling of an accelerator driven system (ADS). Practically computations of such systems, such as energy balance and neutron with radiotoxicity of spallation products, damage and activation calculations depend on nuclear data, and the provision of this information to the engineering community in a form that produces macroscopically transfer and an activation account is a task for assessing nuclear data. Nucleon induced reaction experiments have been implemented because of in the second half of this century has resources of high energy bigger than 20 MeV and are as yet implemented.

This experiment has been conducted; the main purpose of these experiments is to promote basic knowledge of direct reactions, nuclear physics in general and nucleon-nucleon interactions. The various accelerator based nuclear energy applications that have come out in the past decade provide a new application justification of these measurements. The dissimilar accelerator based nuclear energy applications that have emerged in the past decade provide a modern application best reason of these measurements (Patrick 2017). Transmutations of long lived actinides and fission produces from nuclear waste or thorium as an energy source are being inspected with rising interest in the latest two decades.

Different notion of transmutation involve and the Accelerator Driven Systems based on a subcritical nuclear reaction (Rubbia et al. 2004), (Nifenecker et al. 1999). The Accelerator Driven Subcritical Systems have given a modern look at the employ of thorium fuel cycle in a lead–bismuth coolant climate. In parallel to the accelerator driven subcritical systems (Sinha and Kakodkar 2006), (Saha and Sinha 2005) and (Dulera, Basak, Kelkar and Sinha 2005) to advancement reactors require enhanced nuclear data (Ganesan 2004; 2005) that overlap with the on-going international efforts to improve innovative, inherently safe, reproduction resistant and long-lived cores, with features utilizing thorium like in International Project on Innovative Nuclear Reactors and Fuel Cycles (INPRO) and after that generation nuclear energy systems famous as "Generation IV".

The function of the spallation target is to transform (1 GeV) protons produced by the proton accelerator to low energy (less than 20 MeV) neutrons and distinguish them to the energy amplifier area. The effective transformation of fertile to fissionable nuclei or the transmutation of radioactive nuclei to stable ones takes place in the Accelerator Driven Subcritical System blanket favorably in the resonance power area (less than 50 keV) and thermal regions where the capture cross section is the greater. In executing this designing function, the spallation target must be cooled adequately. Nuclear data to [forecast nuclear collision, isotope produce, formation of gases and heat reproduction] are requirement at that first step. Nuclear data are too needed to decrease the hazard related to radiological releasing or other harmful outcome like, for example, that are resulting from off-normal status [loss of coolant in the target, Non-modified proton beam with respect to time and spatial distribution]. Maximizing neutron and alpha particle production are one of the tasks for a target designing. The chosen of high atomic number Z material is preferred, as the target should have a large number of nucleons per proton (Nucleon/proton) to reason intra-nuclear reactions. For such energy types, the proton expels bound neutrons directly. Accordingly, the emitted neutrons tend to be forward pointed and have rise energy up to the proton energy.

On the other hand, Accelerator Driven System is a newest nuclear reactor which study to creation energy and transformed radioactive waste also is important for starting to breed the necessary U-233 in a Thorium (Th) based type of fuel cycle. (Barros et al. 2010). The concept of Accelerator Driven Systems integrated a particle accelerator with a subcritical

core. Most offers suppose proton (p) accelerators, delivering continuous-wave beams with energy nearly around 1 GeV.

The accelerator has two dimensions; either a linear accelerator or a circular accelerator (cyclotron). High potential accelerator has been under continuous evolution, and the construction of machines with the required specifications. The protons are injected onto a spallation target to product source neutrons for driving the sub-critical core. The target is made of heavy metal in solid state or liquid state. In every proton incident; the spallation reactions in the target are not emitted by many neutrons, which are inserted into the sub-critical nucleus to induce further nuclear reactions. However, the core is very similar to the critical reactor in the subcritical state. It can be designed to operate either with a thermal or fast neutron spectrum. An Accelerator driven subcritical reactor ability meant a nuclear squander handling or energy production, is constituted of this assemblage (a spallation target, a high power proton driver, a sub critical reactor and nuclear data), (Meot et al. 2015).

2. LITERATURE REVIEW

(Boudard et al. 2002) reported that a modern version of the intranuclear cascade model is proposed for the explanations of spallation reactions. Spallation reactions are one branch of nuclear reactions. Compared to the preceding version, it combines new features; (1) it can conform to a spread nuclear surface; (2) the treatment of the Pauli blocking effect gets better; (3) impacts or collisions between dynamic spectator nucleons are clearly suppressed; (4) improved pion dynamics, essentially related to the delta lifetime. Furthermore, another important advantage is the self-proportionate determination of the stopping time. Utilized the evaporation code with forecasts of the model are tested against a large body of experimental data in a range from 200 MeV to 2 GeV for incident energy per nucleon then including total reaction cross sections are composite double differential cross sections, neutron, proton and particle multiplicities.

Double differential cross sections for light particles (proton, deuteron, triton and alpha) also neutrons were produced by bombardment of an incident proton beam at 62.9 MeV which was calculated at the CYCLONE facility in Louvain-la-Neuve in Belgium (Guertin and Arnaud et al. 2005). These calculations have been executed using two independent experimental set-ups including; (1) neutron (Demon counters); (2) light charged particles (Si-Si-CsI telescopes) detection. The light charged particle data was calculated at nearly eleven various angular positions from 25° - 140° allowing the determination of angle differential cross section, energy differential and total production cross sections.

(Kenji Ishibashi et al. 1997) reported that the calculated double differential cross section $d^2\sigma/dE.d\theta$ of neutron production were calculated for the spallation reaction induced by (0.8, 1.5, 3.0) GeV protons on the targets (Al, Fe, C, Pb). The experiments were completed by time-of-flight technique with an exemplary flight path length of one meter (1m), and the cross sections were acquired with energy resolution better than (8) percent at

neutron energies below 100 MeV. The experimental data was compared with the outcomes of computation codes based on an intranuclear-cascade evaporation model.

(Tashenov and Stanislav et al. 2011) reported that atomic field bremsstrahlung has been calculated with a longitudinally polarized electron beam. The interconnection between the initial orientation of the electron spin and the angle of photon polarization has been calculated at the photon high energy tip area. In the reflection time this agree to a so-far unobserved phenomenon of output of longwise polarized electrons by photoionization of unpolarized atoms with linearly polarized photons. The consequences emphasize the completely relativistic computations for radioactive re combination and propose a modern method for electron beam polarimetry.

(Niita et al. 2006) were presented three applications of the codes; are spallation neutron source, heavy ion therapy, space radiation. New evolution of the multi-purpose Monte Carlo Particle and Heavy Ion Transfer code System, PHITS was also presented in this study. In particular, they discussed in detail the expansion of two new models, JAM and JQMD, for high energy particle interactions, incorporated in PHITS which compare model computations and experiments for the validations of these models.

(Röder et al. 2013) presented that a convergent experimental and theoretical research of ionization by 40 eV incident energetic electron of the ground state. Absolute (in and out) of-plane measurements are provided for slow electron energy at 4 eV. These are set up to be in best agreement with the convergent close-coupling (CCC) computations.

The report (Gibson and Reid 1986) presented the cross section calculations for the ejection of electrons and angles from 5 to 100 eV and 0 to 100 degrees, respectively. Helium atoms bombardment by protons energies range from 20 to 100 keV with differential in the angle of electron ejection and energy. The measurements were instilled by comparing the assessments of the total cross section, derived from double integration of the measured distributions with published absolute values of the ionization cross section. Although the energy distribution agrees with the available data, there was a substantial divergence in the angular attitude.

The research that was reported by (Fernández-Mencherero and Otranto 2014) is about a theoretical study of completely differential cross sections for the single ionisation of O-H-O by collisions with H^+ and He^{2+} at an effect energy of (2, 6) MeV/amu. In that research double differential cross sections in terms of the electron emission angle are also offered for this molecular orbital (1B1, 1B2, 2A1 and 3A1), which indicate almost isotropic distribution for the electron energies under discernment.

(Sarpün et al. 2014) investigated that the double differential cross section for these elements are (O^{16} , Al^{27} , Ni^{80} , Sn^{120} , $Fe^{54,56}$, Au^{197} , Bi^{209} , Pb^{208} and Y^{80}) by TALYS code program at 62 MeV proton energy. The computation involved the Hauser-Feshbach and the pre-equilibrium exciton model was also measured by TALYS code. The calculated outcomes were compared with the experimental data. Likewise, the results were in good agreement.

(Demirkol and Eyyup 2011) multiplicities of neutron and different particles per incident proton in collision of (15×10^2) MeV energetic proton beam for such thin targets (Au, Pb, W, Bi, Th, U, Fe and Cu) have been approximated with the models ; Cascade-Exciton Model, intranuclear cascade and Evaporation model. The computation have been made utilizing simulation codes based on specific models which characterize elementary output of particles in nuclear reactions. The acquired results have been compared with the available data.

(Junghans 2014) reported that studying nuclear reactions in the ranges of several keV kinetic energy, the neutrons produced by the reactions that below requirement were slowed down by elastic collisions with light nuclei. Spallation reactions and photonuclear could product a beamy spectrum of neutrons with height density, while from the fusion of this isotopes "Hydrogen" for instance $D(t, xn)$ Helium-4 or transformation reactions such as ${}^7Li(p, xn){}^7Be$ quasi-monoenergetic neutrons ability to be produced. Utilize of a pulsed beam allows to determined the neutron energy through measuring the time-of-flight of the neutrons with a known flight path. Photo-neutron sources utilize typically an electron linear accelerator to make intensive pulses of "electromagnetic radiation produced by the acceleration " in an intense metal target that also acts as the neutron radiator

in which neutrons were produced by (p, xn), (n, xn), and (α , xn) reactions with the heavy nuclei.

(Demirkol 2006) were measured the production cross sections of intense remaining nuclides in the p + Pb²⁰⁸ for (1GeV/nucleon) reaction. The computations were equipped with the Cascade Exciton Model computations the pre-equilibrium effect, the Intranuclear Cascade Model, the empirical, and the semi-empirical parameterization. The outcome of the cross sections acquired were compared with the available experimental data, and the relevance between them was calculated.

(Drosg and Hoop 2016) calculated cross section and double differential cross section from triton bombardment of Au-197 that were concluded from measurements of triton interactions with gas targets that utilized Au-197 as a triton beam stop material. That process used for produced neutron. For calculated differential cross section the energies (5.97, 7.47, 10.45, 16.41, and 19.14) MeV tritons on ¹⁹⁷Au for production neutron were used.

(Getahun 2011) reported that a calculations of the excitement function of [⁹³Nb(α , n)⁹⁶Tc, ⁹³Nb(α , 2n)⁹⁵Tc, ⁹³Nb(α , 3n)⁹⁴Tc] reactions have been executed in the incident alpha energy range from 10 to 42 MeV. The computations were utilizing ALICE-91 computer code program. In these calculations used pre-equilibrium nuclear models. The nuclear models includes: (1) Intra-Nuclear Cascade (INC); (2) Harp-Miller-Berne(HMB); (3) Exciton model; (4) Geometry Dependent Hybrid (GDH).

(Kerveno et al. 2002) studied that the calculations double differential cross sections for hydrogen isotope production have been ejected in 62.7 MeV neutron induced reactions on a lead target. The angular distribution from 20 to 160 for eight angles allowing the taking out of (total production cross sections, angle differential and energy differential) has been calculated. A first set of comparisons with several theoretical computations is also offered.

(Abdelbagi 2017) calculated the neutron total cross section experimentally based on Transference and assimilation of intensive neutron beams. This study present the funda-

mental atomic nucleus radius experimentally utilizing plutonium-beryllium source by comparing the Ramsauer model computation for the elements C, Al, S, Fe, Cu, Hg and Pb and neutron wavelength. In this investigation, the experimental methods were compared to the Ramsauer model.

(Patrick 2017) provided that a Measurement of the Antineutrino Double-Differential Charged-Current Quasi-Elastic Scattering Cross Section at Minerva. This thesis characterizes a measurement of a charged-current double-differential antineutrino scattering cross section on carbon scintillation at the Minerva detector at Fermilab.

(Wachter et al. 2015) reported that a measurement of the experimental production cross-section of the reaction $Zn^{nat}(p, x) Ga^{67}$ has been calculated in the energy range from 1.678 to 2.444 MeV. In this investigation X-ray emitted after radiation by the daughter nucleus that decays through electron capture. In this study used the ALICE/ASH and Talys-1.6 computer code then compared with experimental data.

(Sümmerer and Blank 2000) reported that a modern experimental data acquired fundamentally at the GSI/FRS facility allow to modify the experimental parameterization of spallation cross sections. It will be shown that minor modifications of the parameters lead to a so best reproduction of calculated cross sections.

(Taieb et al. 2003) investigated that spallation evaporation reaction by heavy nuclide production such as U-238 induced by 1 GeV energetic protons was calculated in inverse kinematics. The evaporation remains from tungsten to uranium were specified in-flight in mass and atomic number. It was also determined production cross-sections and the momentum distributions were also determined. During the study, the data was compared with experimental data. A comparison with previous results from the spallation of ^{208}Pb and ^{197}Au reveals the strong influence of fission in the spallation of ^{238}U .

3. MATERIALS AND METHODS

3.1. Nuclear Reaction

When two nuclei, overcome their Coulomb repulsion, come within the variety of the nuclear force, a reorganization of nucleus maybe happen. This may product in a nuclear reaction, similar to the reorganization of atoms in reacting molecules through a chemical reaction. Nuclear reactions were generally produced by bombarding a target nucleus with a nuclear projectile in most cases a nucleon (proton or neutron) or a light nucleus for instance, a deuteron or α - particle.

A nuclear reaction was characteristically represented as; $X(a, b)Y$. In which an incident particle a, and interacts with the target nucleus X emits an resulting particle b, then leaving behind the remaining nucleus Y, this is usually written in one of two ways:

Where:

a = a projectile

b = an emitted particle

X = target nucleus and

Y = the residual nucleus.

Two quantities are very important for energetic considerations in evaluating a nuclear reaction:

- (1) The threshold energy is the minimum projectile energy essential to satisfy mass energy and momentum protection in a nuclear reaction to form products in their ground state.
- (2) The excitation energy is the surplus energy over the ground state for the production of a nuclear reaction.

Generally, should be known the system before and after the reaction however what punctually occurs during the reaction process is not known. It also is impossible to look into the reaction process immediately, models for reaction mechanism is suggested to demonstrated the product and angular and energy distributions of the reaction productions. The initial tried for model a reaction was made by Niels Bohr (Bohr 1936).

Nuclear reaction occurs in two steps:

1. The projectile was absorbed by the target nucleus and a compound nucleus was formed and a thermodynamic equilibrium was established.
2. The compound nucleus decays by emitting particles or by radiations. It was supposed that the decay of the compound nucleus depends only on the excitement energy and other perfect quantum numbers of the compound nucleus and which was completely freelance of its mode of forming. Also, it was described "independent hypothesis".

In the compound nucleus mechanism, the calculations are well the isotropic distributions of emitted particles in the center of mass framework at bring down excitement energies. Nevertheless, at relatively higher excitement energies, the forward peaked angular distribution of particles show the existence of direct reaction mechanism (Lane and Lynn 1959), (Fesbach 1992). The system is completely in the complex nucleus mechanism, however only a few nucleons participate in the direct reaction mechanism in the development of interactions. The consequences of modern measurements were explained the presence of reaction process which was intermediate between these two extreme reaction mechanisms. The continuous particle spectra illustrates the existence of that more than one step process which was indicates in reaction process started by a few tens of MeV. Preequilibrium or precompound particles were the particles which were emitted during the equilibrium; this process is called preequilibrium nuclear reaction (Fesbach 1992), (Kabach 1995). A drawn representation of the advances of a typical nuclear reaction produced by a medium energy proton is shown in (Figure 3.1).

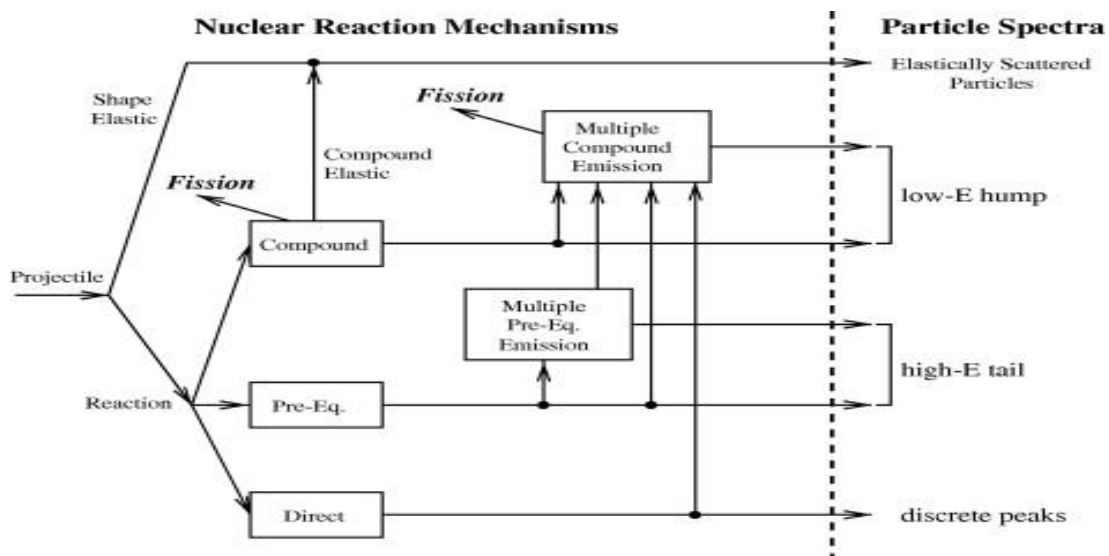

Figure 3.1. Advances of typical nuclear reaction produced by a medium energy protons (Gadioli and Hodgson 1992)

3.1.1. Direct Reaction

(Getachew 2011). When a projectile and a target nucleus were in the range of nuclear forces for the extremely short time, then allowing for an interaction of a single nucleon only. This type of reactions are called "direct nuclear reactions". The remaining nucleus is only the coupled produce of the cluster with the ground state of the object nucleus. This form is normally hard to meet for transmit reaction involving large numbers of nucleons.

There are many properties of direct reactions are ;

- 1- The emission of much larger number of high energy particles than are expected from evaporation model.
- 2- All of particles emission in forward direction (approximately $\theta=0^\circ$ or 10°) then the angular distributions of emission particles illustrate a forward option ($\theta=0^\circ$).
- 3- Energy increases with a monotonic of cross section.
- 4- Generally high energy of projectiles is caused to occur direct reactions.

3.1.2. Compound Nucleus

Calculation of reaction cross sections theoretically developed by Weisskopf and Ewing (Weisskopf and Ewing 1940) is consistent with the Bohr's model (Bohr 1936) utilize partial wave analysis. In the compound model the conservation of angular momentum and evenness for each partial wave is not acceptable. Nevertheless, it gives a better estimate for the magnitude of the cross section. Otherwise, Hauser-Feshbach theory (Hauser and Feshbach 1952) treated the problem in a more exhaustive method and has clearly in use interested the conservation of angular momentum and parity. The compound nucleus might exist to describe by statistical mechanics because of a state of statistical equilibrium. The compound nucleus has life- time nearly gets to ($\sim 10^{-16}$) second as well as it will decay into various channels; however, it will depend only on the angular momentum, energy of excitation, and parity.

3.2. Stopping Power

An accelerator beam pass through a target will lose energy. This energy loss is due to scattering at electrons and nuclei with the electronic stopping most outstanding almost every energy regions. The energy loss at a given energy is commonly expressed in terms of the stopping power which can be defined as the energy loss per given amount of material. The energy loss itself depends on the energy or more precise the velocity of the beam. The average at which a particle loses energy per unit path length is known as the stopping power of the medium. A quantum mechanical derivation including relativistic effects is known as the Bethe - Bloch formula (Cottingham and Greenwood 2001).

$$-dE/dx = ze^4/8\pi^2 (\epsilon_0)^2 (4\pi Z\rho N_A/ Amv^2 [\ln(2mv^2/ I) - \ln(1-\beta^2) - \beta^2]) \quad (3.1)$$

Where:

ze = Charge of the charged particle or ion charge

Z = atomic number

A = mass number

ρ = density of the stopping material

N_A = Numbers of Avogadro

m = electron mass, and

v = Velocity of the charged particle or ion velocity.

For electron account by Bethe-Bloch formula should know these information (Ershaidat 2006):

- 1- The heavy particles have a higher mass than the electron.
- 2- The electron is very similar to the particles with which it is interacting, therefore giving the option of the exchange of identity.

3.3. Charged Particle Range

The range of a charged particle can be derived from the stopping power formula, as defined in the following expression.

$$R = \int dx = \int_E^0 \frac{dE}{dE/dx} \quad (3.2)$$

The range R defined in equation (3.2) is inversely dependent on ρ (the density of the stopping medium), since the stopping power (dE/dx) depends immediately on ρ as it is showed in equation (3.1). The range R is differently dependent on ρ in these two equations (3.1) and (3.2) since, the scattering process is statistical, and ions will be spread out over a certain range width, if stopping in matter. Near the end of the path, when most of its energy has been comes to down, $-dE/dx$ get to maximum, corresponding to the peak in energy loss at low energy, after which kinetic energy goes from down to zero as the particle comes to rest (Lee 1963). An example of this behavior showed in Figure (3.2) its form was known as the Bragg curve for an α -particle of more than a few MeV of initial energy.

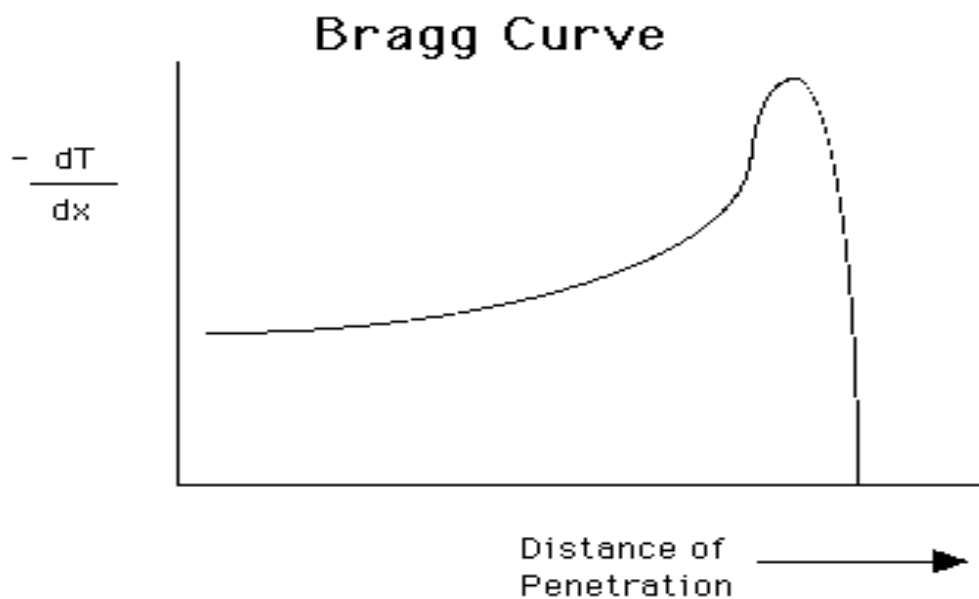

Figure 3.2. Bragg Curve is characteristic for intense charged particles and schemes the energy loss throughout its travel through matter (Wagenaar 1995)

The most important factors affecting Range (R) are:

- 1- Energy: the range is approximately linear with energy since the Bethe Bloch formula for stopping power is inversely proportionate to kinetic energy E.
- 2- Mass: the electron is alot faster than the alpha because of it has smaller mass, and also the electron has less time to spend nearby orbital electrons. This decrease by the effect of Coulomb interactions, and increases range. All of these truly for the same kinetic energy.
- 3- Charge: the more stopping power, the lower range and the more charge then Range is inversely proportionate to the square of the charged particle. For instance, a radioactive isotope of hydrogen a tritium particle with atomic number ($z = 1$) will have (1/4) the stopping power of a He-3 particle with atomic number ($z = 2$).
- 4- Density: the stopping power directly proportional with density, it means that, the stopping power increases with increasing density. However, the range is inversely proportional with density of the absorbing medium (Ziegler 1988).

3.4. Nuclear Level Density

Nuclear level densities play an important role in estimating nuclear reaction cross sections in general. The nuclear level density is the number of levels per unit energy interval. The nuclear power state perhaps is dividing into two regions. When the number of levels is limited then the state up to certain excitement energy (usually between 1 and 2 MeV), it is comparatively well separated. In this energy region the levels densities are comparatively modest in structure, while can be understood on the foundation of nuclear models. Number of levels increases with increases excitement energy and the spacing between them decreases while the nature of excitation becomes much complex. Consequently at high excitement energy the only way to explain them is utilizing a statistical procedure. The concepts of level density were introduced by Bethe (Bethe 1937) for function ρ in this form

$$\rho(E) = \frac{dN(E)}{dE} \quad (3.3)$$

Where $N(E)$ is the accumulative number of levels bring to the excitement energy .

3.5. Cross Section of Nuclear Reaction

The cross sections in nuclear reaction utilize to describe the probability that a reaction will occur of nucleus (Lane and Thomas 1958). Furthermore, the area of the target nucleus able to be seen by the incident particle is proportionate to the rate of reaction; as well the term of the cross section is utilized to denote a constant related to the rate of a reaction. The unit of the cross section more often is used the (barn) (Basdevant, Rich, and Spiro 2005);

$$1 \text{ b} = 100 \text{ fm}^2 = 10^{-28} \text{ m}^2 = 10^{-24} \text{ cm}^2$$

On the other hand, the probability for a nuclear reaction is characterized in terms of a cross section, indicated by σ , in fact the proportional cross sectional area given by the target to the arriving projectile.

As a nuclear reaction includes a collision between two nuclei, these correspond to a second order rate law. The cross section is defined by (Vértes et al. 2010):

$$\sigma = R/ I \quad (3.4)$$

Where:

σ = the cross section,

I = the number of incident particles per unit area, and

R = the number of reaction per unit time per nucleus.

Generally, the probability of a reaction is extremely dependent on the energy of the projectile, in addition to what the projectile is.

A different amount of interest is the microscopic cross section, defined as the produce of n ; it is number of atoms per volume and cross section. A beam of a given form of particle can induce a lot of various types of nuclear reaction in a particular target (Kox et al. 1987), so that it is means if the material contains various kinds of objects (i) then the probability to interact is only the summing (Σ) of the probability on each type. Summing is related to the microscopic cross section (σ) by the relationship shown below (Handbook 1993).

$$\sigma_{\text{tot}} = \Sigma_i \sigma_i \quad (3.5)$$

In addition, there are different types of cross section (Nuclear Reactions Some Basics; (<https://facultystaff.richmond.edu/~ggilfoyl/research/nuclearCrossSections.pdf>):

- 1- Total cross section (σ): detect reaction products in 4π .
- 2- Differential cross section or angular distribution ($d\sigma/d\theta$): detect only reaction products emitted at θ in a solid angle $d\theta$. The unit of it is (mb/sr).
- 3- Double differential cross section ($d^2\sigma/dE.d\theta$): is proportional to the number of incident probe particles scattered within an energy range ΔE and momentum variation into a solid angle $\Delta\theta$. The unit of the double differential cross section is (mb/MeV.sr).

4- Triply differential cross section: The formula for $(^3\text{He} (e, e', p) ^2\text{H})$ is $[d^5\sigma/d\theta e' \cdot d\theta p \cdot dE']$. The unit of this type is (mb/MeV.sr²).

3.6. Spallation

3.6.1. The Historical Note About Spallation Reaction

At the beginning in 1930's the particle cascades in cosmic ray interactions was observed. At the earth's surface (Rossi 1933), the thermal neutron flux density outputted by cosmic ray-protons is nearly amount 10^{-4} to 10^{-3} neutrons cm^{-2}/s (Masarik , Kim and Reedy 2007). BB. Cunningham at Berkeley in 1947 discovered the first accelerator driven spallation reactions (Cunningham et al. 1974). Then theoretical characterization was given quickly after by Serber (Serber 1947). In the same year Sullivan WH and Seaborg GT invented the term "spallation" (Harvey 1959).

Spallation reactions have been studied for a lot of years, but it has not been exactly explained yet. They are being studied with the rising utility in the last two decades, as the spallation applications require additional exact knowledge.

Spallation neutron sources are of utility for; (1) transmutation of long lived actinides, (2) fission production from nuclear waste (Bowman et al. 1992), (3) plutonium from nuclear weapons (Krása 2010), (4) thorium as an energy source (Carminati et al. 1993), (5) material research and industry (Mason et al. 2005), or medicine for radiotherapy (Angelone Atzeni and Rollet 2002).

3.6.2. Spallation Reaction

The spallation reactions are one sector of the nuclear reactions. It is a practicability in which a light projectile like, proton, neutron and or light nucleus with the kinetic energy from a number of hundreds of MeV to several GeV interacts with a intensive or heavy nucleus for instance, pb while causes the emission of a big number of hadrons (especially neutrons) or fragments. Spallation reactions play a significant role in a broad field of applications for instance, simulation of detector set-ups in nuclear also particle physics experimentation, neutron sources for basic science, radioactive ion beam and material radiation otherwise ADS (David et al. 2011).

In 1974 at the University of California occurs early study of spallation reaction (Brobeck et al. 1947). Furthermore, a spallation reaction has three stages (Cugnon 1993): (1) intra nuclear cascade, (2) pre-equilibrium stage, and (3) evaporation or fission, (2) and (3) called Deexcitation, as shown in schematic view in Figure 3.3 of spallation reaction.

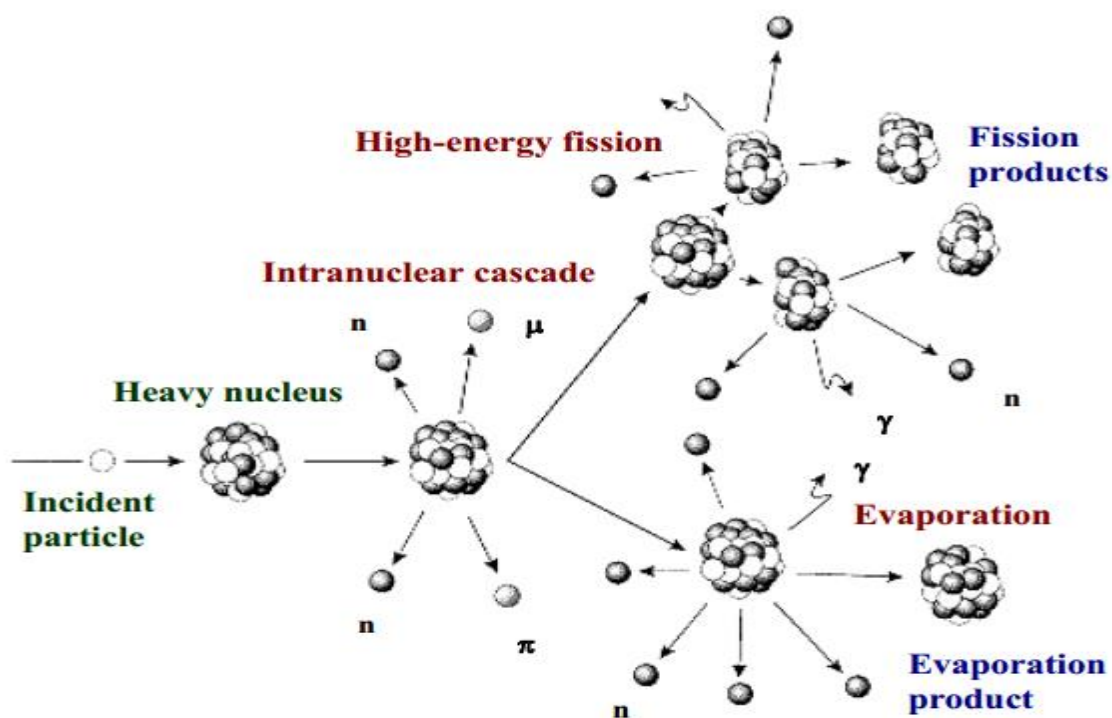

Figure 3.3. The scheme of a spallation reaction (Krása and Rez 2010)

3.6.2.1. Intra Nuclear Cascade (INC)

The Intra Nuclear Cascade process is foundation on the ideas of Heisenberg and Serber, who viewed intranuclear cascades as a sequence of consecutive quasi-free collisions of the quick main particle with the individual nucleons of the nucleus. It is a speedy direct step (nearly amount 10^{-21} s), illustrated in Figure 3.4. As the reduced de Broglie wavelength nearly amount ($\sim 10^{-1}$ fm), if the energy of proton is nearly amount (~ 1 GeV). All interactions take place only between nucleons if the process at low projectile energies, for example nearly amount (~ 100 MeV), then the process is called nucleon cascade. When incident particle energy rising in a gradual way, then the threshold energies for particle produce in nucleon-nucleon impact are being exceeded.

At beginning, pion is coming at energies of about hundreds of MeV, subsequently at larger energies nearly amount 2 to 10 GeV, heavier hadrons are being produced. It can ability also contribute in the intra nuclear cascade and interact between every other, which was called hadron cascade. Particles that acquired energy height sufficient to fleeing from the nucleus are being emitted fundamentally in the direction of the incident particle. The rest of the energy is equally distributed between nucleons in the nucleus which is left in an extremely excited status. The intra nuclear cascade (INC) is not stridently separating from the equilibrium decay.

In a pre-compound step (lower than 10^{-18} s), also the pre-equilibrium emission can happen. During this stage, speedy particles or fragments perhaps emitted after all interaction among the incident or other cascade particle and a nucleon inside the nucleus. The energies of particles emitted during the equilibrium decay are lower than the energies of pre-equilibrium particles.

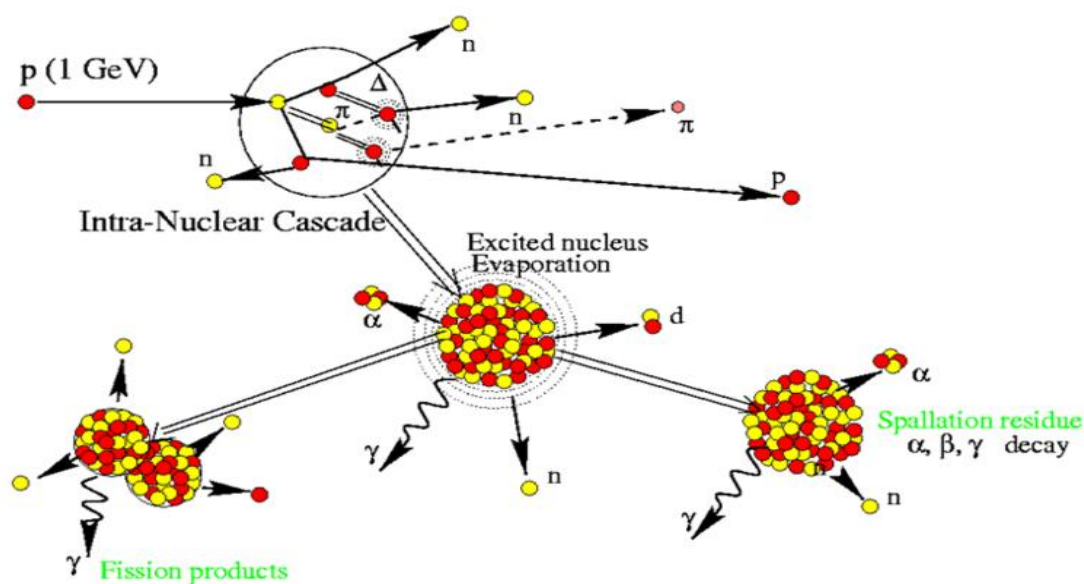

Figure 3.4. schema of Intra Nuclear Cascade (Krása 2010)

3.6.2.2. Deexcitation

After the intra nuclear cascade, the equilibrium stage comes up. Energy is evenly distributed over the nucleus that is in an extremely excited state with small angular momentum. Evaporation of neutrons or light charged fragments are caused for loses nucleus energy (Adair 1954).

Competitive process to evaporation is fission (into two fragments identical in proton number). Fission production as well undergoes evaporation (depending on their excitation energy). When the nucleus does not have to energy sufficient to emit neutrons (its binding energy becomes bigger than the excitation energy), it deexcites by β - and γ -transformations.

Finally, two sections of main important in spallation reactions are: residual nuclei or (spallation products) and emitted neutrons or (spallation neutrons) (Krása 2008).

3.6.3. Spallation Products in Nuclear Reaction

For the duration of the spallation process without neutrons also protons and other light nuclei are emitted from the excited nuclei (Bauer 2001). On the other hand, spallation products spread out in two regions of the table of the nuclides: (1) the heavy proton remains produced from evaporation; it is called spallation evaporation products. (2) The medium mass remains produced from fission, it is called spallation fission products.

The spallation products enable measured utilizing two procedures: direct kinematics (Titarenko et al. 1998), (Michel et al. 1997), or inverse kinematics (Enqvist et al. 2001).

3.6.3.1. Direct Kinematics

In direct kinematics process, a relativistic light projectile hits a heavy target. Using Mass spectrometry and γ - spectroscopy for detected the spallation products which stop in the target. This process has the prospect to measure the productions of the meta-stable states of remaining nuclei, which is able to utilize radioactive targets, and it wasted minimal beam time. However, it is impossible to measure the yields of (extremely long-lived, stable, and very short-lived nuclei, and the off-line outputs) measurements are more time consumption (Krása 2008).

3.6.3.2. Inverse Kinematics

In the process of inverse kinematics, a relativistic heavy nucleus hit a light target. The spallation products desertion the target in forward direction and can be recognized instantly in flight utilizing the suitable technique. [Example, the magnetic spectrometer FRS "Fragment Separator" (Geissel et al. 1992) equipped with an energy degrader, multiple-sampling ionization chambers, multi-wire proportional counters, two position scintillator detectors] can be specified directly in flight.

3.6.4. Pre-equilibrium in Nuclear Reactions

Pre equilibrium reaction is not direct reaction or compound nuclear reaction however in some cases it is likely for particles to be emitted after the first stage of a nuclear interactions but before the realization of statistical equilibrium or compound nucleus forming. Statistical decay of the compound nucleus and the instant emission after collision is neither by emission of particles from the excited target nucleus in pre-equilibrium reactions. Also, the emission of a particle by the target nucleus occurs is not instantly after the collision or by the statistical decay of the compound nucleus.

The projectile splits its energy between a small numbers of nucleons in the target. The hitter nucleons start a cascade of reactions in the target, at the course of which a particle can be emitted (before the compound nucleus has arrived at a case of statistical equilibrium). The pre-equilibrium effects beginning evidencing themselves at energies approximately 20 MeV, and at excitation energies over 50 MeV their contribution starts becoming important. It is supposed that every probable methods of distribution of the excitation energy among every various particle-hole arrangements with the equal exciton number have equal possibility to happen. Also, the pre-equilibrium models are very essential instrument to analyze and understand nuclear reactions at excitation energies ranging from several tens of MeV above to the GeV regions (Getachew G. 2011). On the other hand, nuclear reaction models based on semiclassical, also totally quantum mechanical theories are suggested for pre - equilibrium emission mechanism (Bethe 1937).

Several of the significant semiclassical models are (Bethe 1937):

- 1- Intranuclear Cascade Model (INCM)
- 2- Exciton model
- 3- Hybrid and Geometry Dependent Hybrid model (GDH)
- 4- Index Model

3.6.4.1. Intranuclear Cascade Model (INCM)

In 1947 Serber was proposed the first intra-nuclear cascade model (INCM) (Serber 1948) also it is the initial nuclear reaction model that included pre - equilibrium emission. The first computation of pre-equilibrium angular distributions was completed by this model utilizing the quasi-free scattering inside the nucleus. Figure. 3.3, shown the graphic explain the (INCM).

Intranuclear Cascade Models (Gudima, Mashnik, and Toneev 1983), (Bertini 1963), (Yariv and Fraenkel 1981), (Boudard et al. 2002) characterizing interactions among an impinging particle and target nucleons throughout intranuclear cascade as a series of binary collisions separated in space and time. This is proper if a mean free path of the incident particle in the target nucleus is greater than the inter-nucleon lengths then the incident particle wavelength is smaller than a mean distance among nucleons of the target nucleus. The path among collisions is given to be linear.

The collisions progress until an appointed degree of equilibrium is arrived. The standard utilized in the Intra-Nuclear Cascade Model (INCM) of Cugnon (INCL4) is an empirical time of equilibrium (so is called cutoff time, is nearly equal to $T_{\text{cut}} \approx 30 \text{ fm}/c$ that permits five consecutive nucleon-nucleon interactions on the average), which was deduced from a clear change of the studied quantities (Pienkowski et al. 1994). The Intra-nuclear Cascade Model in CEM03 is founded on the standers version of the Dubana cascade model (Barashenkov and Toneev 1972). The CEM03.1 code utilizes a standard for the escape of a primary particle from the cascade stage by the effective native optical potential $W_{\text{opt.mod}}(r)$ determined from the native interaction cross sections, including the blocking effects because of the Pauli Exclusion Principle. The Intra-Nuclear Cascade model (INCM) is a factual model but in general; the model forecasts are not satisfying at backward angles and in several forward angles also. To determine the secondaries produced in the interaction and calculate the momenta of the particles utilizes process classes and model classes. (Getachew 2011). The momenta of the two nucleons contributing in the absorption are chosen at random from the Fermi distribution and the pion energy is distributed evenly among these nucleons in the center of mass system of the three particles contributing in the absorption (Mashni 2005).

To sum up, the fundamental steps of the INC model are abbreviated are (Getachew 2011):

- 1- The space point at which the incident particle enters the nucleus is chosen uniformly above the projected region of the nucleus.
- 2- Total cross sections particle-particle and region-dependent nucleon densities are utilized to select a trajectory length for the projectile.
- 3- The kind of reaction, the momentum of the struck nucleon and the four momentums of the reaction outputs are determined.
- 4- If the Pauli Exclusion Principle permits and $E_{\text{cut off}} < E_{\text{particle}} = 2 \text{ MeV}$, step (2) is performed to transmit the products. Then the exciton model updated as the cascade proceeds.

3.6.4.2. Exciton Model

The Exciton model is offered and first introduced by Griffin in 1996 and later modulate by many researchers. The number of excited particles and holes (the excitons) at any phase of the nucleon-nucleon cascade, in the Exciton model it is called the compound nucleus states. In that model the equilibration among target and projectile is accomplished by the series of nucleon-nucleon interactions (Nigussie 2012). The initial configuration is unchanging by the nature of the projectile. For example in case of a nucleon induced reaction, it is a two particle (2p) one hole (h) configuration because of the interaction of the incident nucleon with a nucleon of the target which is excited from a state below to a state on top of the Fermi energy. Where p is the number of particles and h is the number of holes, then the exciton number (n) is describe by $n = p+h$.

An excited nucleus is considered as a gas of quasi particles i.e., particle-hole degree of freedom is incorporated. In this the nuclear potential is shown with evenly spaced singular particle levels, i.e., levels whose occupancy is each 0 or 1. At first the target nucleus is in ground state. The projectile nucleon enters the target nucleons with a given energy and form a one particle ($p=1$) without hole ($h=0$) state, i.e., a state with exciton number $n = 1$. At this phase, the projectile has entered the nuclear force field but has not been absorbed by the target.

It is still in the entry channel and the field of nuclear force can be left without interaction with any individual target nucleon. As every the levels under the Fermi energy are filled, the first interaction among the projectile and target nucleon will raise the latter on top of the Fermi energy and go away a hole below. The absorption of the projectile nucleon by the target leads to the configuration of $n = 3$ exciton state, it means a $2p-1h$ state is formed (Koning, Hilaire and Goriely 2013). After configuration of the $n = 3$ exciton state any of the excited particles perhaps emitted if it has due energy to escape. If but, particle emission does not occur; consequently there will be an extra two body interaction either between one of the two excited particles and a particle under the Fermi surface or between the two excited particles themselves. For this reason a two body interaction will lead to transitions in which the modification in the exciton number $\Delta n = \pm 2, 0$ (Getachew 2011).

3.6.4.3. Hybrid and Geometry Dependent Hybrid (GDH) Model

The intra-nuclear cascade (INC) computation outcomes indicated that the exciton model shortage resulted from a failure to satisfactorily reproduce enhanced emission from the nuclear surface. So as to provide a first order correction for this deficiency the hybrid model was reformulated. This model was redrafted and it was proposed by Blann and vonach (Blann and Vonach 1983).

The Hybrid Model preserves the physical transparency and ease of the exciton model while permitting the calculation absolute spectral produce as in the Harp-Miller-Bern (HMB) model. The continuum decay rates are calculated from the partial state densities while the intra-nuclear transmission rates are calculated from the mean free path of the nucleons in the nuclear matter. The mean free path, in turn, perhaps estimated either from free nucleon - nucleon scattering cross sections or from the imaginary part of the optical potential (Gadioli and Hodgson 1992). Furthermore, this model multi pre-equilibrium particle emission beside with equilibrium decay is considered while the spectra of emitted particles are computed for all steps in the energy dissipation process induced by the interaction among projectile and target nucleons.

On the other hand, the ability of the hybrid model of pre-equilibrium nuclear reaction to predict unidentified excitation functions and to perform alpha priori computations of nuclear reactions cross sections for a wide diversity of reaction sorts is an outstanding feature of this model. Other than, there are distinct dissimilarities in the quality of such computations depending on the type of bombarding particle and on the excitation energies of the reacting systems (Michel et al. 1985). The geometry dependent hybrid model is a variant of the hybrid model in which the nuclear geometry effects are considered.

In hybrid model computations the nuclear matter intensity is taken as consistent throughout the nucleus while the geometry dependent hybrid (GDH) model takes into calculation the reduced matter density and hence also the surface potential at the nuclear surface.

3.6.4.4. Index Model

Index model was developed by Ernst (Ernst et al. 1987), of independently interacting excitons, for pre equilibrium emission which unifies the exciton and hybrid models. The basic supposition of the index model is that every excited particle which survives emission experiences two - body collisions and generate further particle (p), hole (h) pairs independently from each other. Thus the energy of all exciton is shared by the three excitons of the subsequent phase.

The average nucleon - nucleon collisions rates and the interior energy in this model are possessed from the interaction rate of nucleons inside the nuclear matter. This model is not generally utilized as compared to exciton and Geometry Dependent Hybrid model (GDH) (Ernst et al. 1987).

3.7. Accelerator Driven System (ADS)

3.7.1. The Historical Notes About ADS and Transmutation

That the bombarding of uranium target by high-energy protons would generate major yields of neutrons studied by researchers in the 1940s. The neutrons output by these reaction could be utilized to produce fissionable material through nuclear reactions. Glenn Seaborg produced the first man-made plutonium in 1941, using an accelerator. In the period 1950-54, the Materials Testing Accelerator (MTA) program at Lawrence Livermore National Laboratory in California in 1950 (Heilbron et al. 1996) examined in detail the utilize of accelerators to generate fissionable material. Nearly at the same time as in Canada, Lewis realized the assessment of accelerator breeding in the power programmed and initiated spallation neutron yield measurements with the McGill cyclotron. The project ended in 1954 and the documents were declassified in 1957.

Lawrence et al, suggested to radiate different thick targets such as (U, Be and Li) by protons and deuterons to measure the cross-sections, neutron yields, and the feasibility of changing the fertile (depleted uranium or thorium) to produced or fissile material Pu^{239} , U^{233} respectively (Rubbia, Aleixandre and Andriamonje 2001). This was the first incentive, because the United States of America (USA) were dependent on overseas uranium sources. A few years later, the MTA project was stopped up when rich domestic uranium ores were found in the Colorado plateau. Over the coming decades, important investigations have been estimation to assess deficiencies in different transmutation modes. For instance, neutron yields and spectra in uranium targets radiated by relativistic protons (Tolstov 1989), (Vasil'kov et al. 1978) and nuclei (Voronko et al. 1991) and neutron cross-sections for a number of isotopes have been measured in JINR Dubna. At the end of 1980's at Japan Atomic Energy Research Institute (JAERI) has started the first fully conceptual and complex research of the radioactive waste transmutation.

Later studies from 1975 to 1988 on the Fertile-to-Fissile transformation (FERFICON) Program - a cooperating attempt with different laboratories - researched the energy dependence, able to 800 MeV, of the fertile-to-fissile transformation capacity utilizing incorporated target materials and geometries (Rubbia, Aleixandre and Andriamonje 2001).

Option Making Extra Gains from Actinides and Fission Products (OMEGA) it is A long-term program for examine and development on nuclide partition and transmutation technology (Mukaiyama 2003). From the beginning of 1990's the OMEGA program which initiated the global interest in transmutation topic. A detailed concept of the Accelerator Transmutation of Waste (ATW), utilizing thermal neutrons have been created by Bowman C, from Los Alamos National Laboratory (LANL), also he proposed the utilize of a linear accelerator with a high-intense proton current nearly amount to (~ 250 mA) of 1.6 GeV energy (Bowman et al. 1992). From European Council for Nuclear Research (CERN), C.Rubbia suggested a basic concept of the Energy Amplifier, also called Accelerator Driven Energy Production (ADEP) (Carminati et al. 1993) illustrated in Figure 3.5. The stimulus for ADEP is comparable as for the MTA project. This conception is based on the utilize of Th^{232} as a fuel for the produce of fissile U^{233} (Krása 2010), it seen by this equation

Figure 3.5. Fast energy amplifier (General lay out of the Energy Amplifier complex) (Rubbia et al. 1995)

3.7.2. Nuclear Transmutation

In 1919 Ernest Rutherford, demonstrated transmutation, as the first, on instance of $^{14}\text{N} + \alpha \rightarrow ^{17}\text{O}$ (Rutherford 1919). Afterward demonstrate the first accelerator-driven transmutation in 1932 by J. D. Cockroft and E. T. S. Walton . They bombarded (Li) target with (125 to 500) keV protons (from linear accelerator) and "transmuted" Li-nucleus into two α -particles (Cockcroft and Walton 1932).

Nuclear transmutation is a process where in the structure of an atomic nucleus changes. The nucleus physics properties are change when changing the number of neutrons such as, activity, half-life and radiation energy. However, when changing the number of protons, the nucleus obtains also different chemical properties for instance, chemical coupling and reaction rate (Krása 2008).

The main advantage of transmutation is a reduction in the minor actinide and long lived fission product content of the High-level waste (HLW). The first and most efficient stage to decrease the total mass of the High-level waste is the transmission from an Light water reactor (either pressurised or boiling) once-through strategy with immediate elimination of the fuel elements to a plutonium burning strategy with High-level waste (HLW) vitrification. Compared with the latest, transmutation strategies have only an unassuming mass reduction potential. While the radiotoxic nuclides in the High-level waste (HLW) are able to only partly be eliminated, transmutation does not make geologic elimination concepts extra, however must be careful as a complementary waste management method which might ease the design and licensing requirements for geologic depository because the geosphere barrier would no longer have a significant safety function.

Transmutation aims at decreasing the radiological impact of actinides and fission products in the High-level waste by nuclear transmutation of trouble some long-lived nuclides in strong radiation fields. (NEA Nuclear Science Committee 2002).

It seems that, suitably induced transmutations could be utilized to reduce the half-lives of long-lived a radioactive isotopes (Table 3.1) included in the high level waste that is being generated during the nuclear fuel burn up in nuclear reactors.

Produced the radioactive nuclei during the operation of nuclear reactors in two ways: Fission products and higher actinides (Krása 2008).

Table 3.1. Fission products and higher actinides consist of in nuclear burnt up fuel, which are predictable for transmutation. The quantities are yearly waste production (after 10 years of decay) from a typical commercial reactor (3 GW power, with fuel burnt to 33 GW days per ton with the yearly removal of 33 metric tons uranium equivalent of spent fuel per year) (Bowman 1992)

Fission product	Half-life [years]	quantity [10^{23} atoms]	Activity [Bq]
Se ⁷⁹	1×10^6	13	3×10^{10}
Sr ⁹⁰	30	900	7×10^{16}
Zr ⁹³	2×10^6	1500	2×10^{12}
Te ⁹⁹	2×10^5	1500	2×10^{13}
Sn ¹²⁶	1×10^5	46	1×10^{12}
I ¹²⁹	2×10^7	270	4×10^{10}
Cs ¹³⁷	30	1400	1×10^{17}
Higher actinide	Half-life [years]	quantity [10^{23} atoms]	Activity [Bq]
Np ²³⁷	2×10^6	366	4×10^{11}
Am ²⁴¹	400	413	2×10^{15}
Am ²⁴³	7×10^3	73	2×10^{13}
Cm ²⁴⁴	20	13	2×10^{15}
Pu ²³⁸	90	113	3×10^{15}
Pu ²³⁹	2×10^4	4160	4×10^{14}
Pu ²⁴⁰	7×10^3	1920	6×10^{14}
Pu ²⁴¹	10	640	1×10^{17}
Pu ²⁴²	4×10^5	390	2×10^{12}

3.7.2.1. Fission Products

Fission products are being produced by the fission of U²³⁵ or Pu²³⁹ in classical or quick nuclear reactors so are mostly slightly over the line of β -stability. To transform them to stable nuclides, they should capture one or more neutrons and then go through β -decay (Krása 2010).

3.7.2.2. Higher Actinides

To transmute higher actinides to stable nuclides, they must undergo neutron capture and in order fission, which is a process that generates energy and makes the transmutation attractive from the point of view of energetic. On the other hand, higher actinides, representing about one per cent of spent fuel, are being generated by the neutron capture within nuclei of U²³⁵, U²³⁸, or Pu²³⁹ and their resulting β -decays (Krása 2010).

3.7.3. Accelerator Driven System (ADS)

The Accelerator Driven System is a modern form of nuclear reactor which produces energy even though it residue sub-critical during its life. Every operating reactor in the world is "critical" reactors, which denote that the number of neutrons generated by fission is precisely balanced by the number absent by leakage and absorption by different materials in the reactor. This balance is accountable for maintaining a constant reactor power at any required level. Sub-critical reactors output a small number of neutrons via fission than are lost by absorption and leakage, and require an external supply of neutrons to preserve a constant reactor power. Interaction of a high energy proton beam with a heavy atom nucleus like lead, it is caused of comes the external neutron supply, and this process in nuclear physics is called spallation. The power level in an Accelerator Driven System (ADS) is bigger for stronger external sources and for reactors which are nearer to "critical". (Nifenecker, Meplan and David 2003).

Cyclotrons, high-energy accelerators or high-current are able generate neutrons from heavy elements by spallation. A number of investigate facilities exist which explore this phenomenon, and there are plans for much bigger ones. In this process, a beam of high-energy protons usually bigger than to 500 MeV is directed at a high-atomic number target such as, depleted uranium, tungsten, tantalum, thorium, lead and mercury and up to one neutron can be outputted per 25 MeV of the incident proton beam. (These numbers contrast with 200 to 210 MeV out by the fission of one uranium-235 or plutonium-239 atom). A 1000 MeV beam will make 20 to 30 spallation neutrons per proton (World Nuclear Association 2014).

Additionally, can be described neutrons produced in spallation reactions by heir energy and spatial distributions and multiplicity. The neutron multiplicity ought to decide the current and beam energy of the proton driver accelerator as their energy and spatial distribution forms the geometry of the spallation target and the protecting to high-energy neutrons (Armbruster and Benlliure 2001). Also, the spallation neutrons have only an extremely very small probability of causing extra fission proceedings in the target (Rhodes 2013). Produced residual nuclei and neutrons also by spallation reactions that are means the Spallation reactions do not only produce neutrons. Mainly of these nuclei are

radioactive. Furthermore, the residual nuclei will contribute to the rust and the corrosion and to the radiation damages in the target, accelerator window and structural materials (Armbruster and Benlliure 2001).

The produce neutrons in the spallation reactions have huge potential in research such as, in energy production, in medical industry, in earth and in space. However, the risk of radioactive waste emerging from nuclear energy production is a subject of continuous discussion and public concern in a lot of countries (Hossain, Taher and Das 2015).

Transmutation of extremely radioactive nuclear waste can be carry out utilizing an accelerator driven system (ADS), when the spallation target impact by high energy protons then produce neutrons. These neutrons are multiplied in a sub-critical core, whereas together fissioning the minor actinides at stable nuclides or short-lived nuclides (Shetty 2013).

The accelerator driven system has recently getting raised interest because of its potential to get better the flexibility and safety Properties of transmutation systems (Hossain, Taher and Das 2015). A subcritical reactor is a nuclear fission reactor that generates fission without realizing criticality. Instead sustaining a series reaction, a sub-critical reactor utilizes extra neutrons from an outside source. Like a reactor coupled to a particle accelerator to output neutrons by spallation is called an Accelerator Driven System (Hossain, Taher and Das 2015).

Consequently, a sub-critical reactor is driven by an Accelerator Driven System (ADS) to recompense for the loss of neutron economy which or else would have been self-sustaining in a critical reactor (Shetty 2013).

Transuranics (higher atomic number than uranium-92, such as "Berkelium" is a transuranic element, atomic number is 97) and mostly minor actinides have such adverse special that they drastically decrease the substantial features capable of moderating and stabilizing the series reaction. Great rewarding exists subsequently, to burn such fuels in dedicated innovative systems with "compact" safety features such in a sub-critical reactor.

There exist different strategies with respect to nuclear power in the member states of the EU. Whereas there are countries that consider nuclear power as a role to a sustained energy stipulation, there are others countries which have today a position aiming to phase out of nuclear energy. Moreover, in several countries plutonium will be recycled either in fast reactors or in thermal while in different countries plutonium is considered as a waste. Partitioning and Transmutation utilizing ADS can play an important role.

The following are essential fundamentals for the development of ADS for the task expects (Kadi and Revol 2001).

1- A greatest beam power in this range of (12 to 40) MW (characteristically a current of 12 to 40 mA of protons at 1GeV) also a spallation target accepting up to 40 MW of thermal power is necessary for an industrial model to be built and operated approximately around 2030. This will agree to use of ADS with a power of (500-1500) MWth starting around 2040.

2- A dedicated fertile free fuel and regarding fuel cycle will be advanced by 2025. ADS prepared with that fuel will have the ability to burn about 12×10^4 g TRUs per TWh_e which is equal to 10^6 g TRUs per GW_e a (nearly around one years).

3.7.4. The Concept of Accelerator Driven System (ADS)

The concept of accelerator-driven systems (often called hybrid systems) comes together a particle accelerator with a sub-critical core. Most suggestions suppose proton accelerators, bringing continuous-wave beams with an energy around 1 GeV. The accelerator is both a linear accelerator (linac) and a circular accelerator (cyclotron). High-power accelerators have been under continuous development, and the building of machines with the necessary specifications (OECD Nuclear Energy Agency 2002).

The protons are inserted upon a spallation target to produce source neutrons for driving the sub-critical core. The target is made of heavy metal in liquid or solid state. Spallation reactions in the target produce a few tens of neutrons per incident proton, which are put in at the sub-critical core to stimulate more nuclear reactions. Excepting for the subcritical state and the core is quite comparable to that of a critical reactor. It can be designed to operate with a fast or thermal neutron spectrum (Shetty 2013).

The energy transformation portion of an accelerator driven nuclear power system is comparable to that of a normal power plant. However, the electrical energy which is recycled to the accelerator reduces the net electrical efficiency of the system in the accelerator driven system. For an Accelerator Driven System with a neutron multiplication factor of 0.95, the decrease amounts to around 12%. This means that the accelerator driven system produces about 14% more high-level waste and refuses about 20% more heat to the atmosphere than a normal power plant with the same net electrical produce (NEA Nuclear Science Committee 2002). Subcritical reactor uses for generated the electric energy as shown in (Figure 3.6).

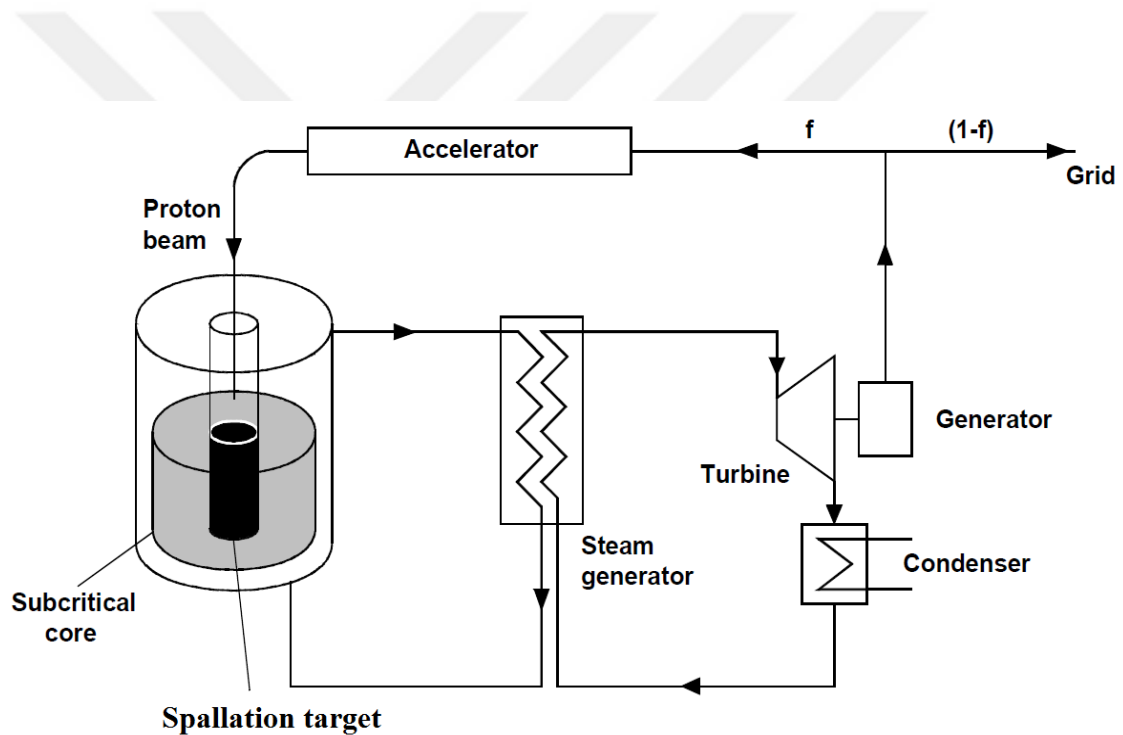

Figure 3.6. ADS based electric energy generation (NEA Nuclear Science Committee 2002)

4. RESULT AND DISCUSSION

4.1. Calculation Method

In the present study, the reaction double differential cross section $d^2\sigma/dE.d\theta$ of intensive elements were calculated by using nuclear reaction models such as; (equilibrium, pre-equilibrium). Excitement functions of double differential cross section $d^2\sigma/dE.d\theta$ for elements Thorium and Boron was calculated using CEM03.01 program. Theoretical calculations of double differential cross section $d^2\sigma/dE.d\theta$ prophesy that most probable energy proton were fundamentally emitted from compound nucleus mechanism while higher energy protons were mainly emitted due to pre-equilibrium and direct reaction mechanism.

The present study describes calculation of the double differential cross section of the secondary particles (n, p, α) occurring after spallation in the reactions $p + {}_{90}\text{Th}^{232}$ and $p + {}_5\text{B}^{10}$. Nuclear model calculations are a major attention in nuclear reaction programmes, especially with regard to their predictive power in event of unknown double differential cross sections $d^2\sigma/dE.d\theta$.

In this study, ${}_{90}\text{Th}^{232}$ and ${}_5\text{B}^{10}$ bombardment by the accelerated proton at different energies is utilized by several energy range randomly. For instance, $p + {}_{90}\text{Th}^{232}$, (p, α) was used in the ranges (20-500) MeV and for that reaction $p + {}_5\text{B}^{10}$, (p, α) was used only at 660 MeV. On the other hand, for $p + {}_5\text{B}^{10}$, (p, n) reactions passed out in the (30, 50 and 186) MeV proton incident energy range. In this study, also all reactions were used at many angles for the calculations such as; CEM03.01 codes.

In addition, compared $d^2\sigma/dE.d\theta$ for ${}_{90}\text{Th}^{232}$ and ${}_5\text{B}^{10}$ in the $p + {}_{90}\text{Th}^{232}$ and $p + {}_5\text{Th}^{10}$ reactions for (p, n), (p, α), (p, ρ) forms at 360 MeV with various angles (0° , 20° , 40° , 60°) respectively.

4.2. CEM03 Computer Program

CEM03.01 is the most modern computer program in a sequence of codes include CEM97, CEM2k+GEM2, and CEM95. It is an prolonged and gets better version of the previously codes, which perform versions of the Cascade-Exciton Model of nuclear reactions. This program considers Intra Nuclear Cascade, preequilibrium, fission, evaporation and Fermi Break-up mechanisms of nuclear reactions as well as coalescence of complicated particles up to Alpha(α) from speedy INC nucleons.

This computer program measures total reaction and fission cross-sections, nuclear facilities, excitation functions, nuclide distributions (yields) of all generated isotopes separately. Furthermore, to their (A) and (Z) distributions, energy and double-differential cross-sections, angular spectra, mean multiplicities, i.e. the numeral of ejectiles per inelastic interaction of the projectile together with the target, ejectile yields and their mean energies for p, n, d, t, ^3He , α , π^+ , π^- , and π^0 . By modifying an input changing, evaporation of as many as sixty isotopes heavier than α (up to ^{28}Mg) perhaps also modeled. Beside that, CEM03.01 provides in its output separately the yields of Backward and Forward created isotopes, their denote kinetic energies, Z and A distributions of the mean emission angle, their parallel velocities, and the Forward/Backward ratio of commonalty products in the laboratory system, distributions of the indicate angle between two fission spall of momentum and angular momentum, of neutron multiplicity, of the excitation energy, and of mass and charge numbers of residual nuclei after the Intranuclear Cascade and pre-equilibrium stages of reactions, as well as for fissioning nuclei before and after fission.

CEM03.01 calculates reactions produced by nucleons, pions, bremsstrahlung and monochromatic photons on not too light targets at incident energies nearly from ~ 10 MeV (~ 30 MeV, in the case of $\gamma + A$) up to various GeVs. (Mashnik et al. 2005). The Cascade-Exciton Model of nuclear reactions was suggested firstly at the Laboratory of Theoretical Physics (Ganesan 2007) to describe average-energy spallation reactions yield by nucleons and pions. It was determined on the Dubna IntraNuclear Cascade and the Modified Exciton Model (Kadi 2001) and (Barros 2010).

4.3. Reactions

4.3.1. $p + {}_{90}\text{Th}^{232}$ Reaction

Thorium is a chemical and radioactive element by indication (Th) and atomic number 90. That occurs naturally in low condensation about ten parts per million in the earth's crust. Thorium in also unmixed appearance is a silvery heavy metal which is about intense lead (pb). In nature, approximately all thorium is ${}_{90}\text{Th}^{232}$, as the same time as several additional isotopes could be present in small quantities. The half-live of thorium-232, the isotope of most concern, is very long. Thorium-232 is present in soil and ore in temporal equilibrium with radium.

The main use of thorium has been in the preparation of the Welsbach cloak for portable gas lanterns. It was an important mix up element in magnesium which used to mantle tungsten wire for components of electronic tools, while it was used for more ways. Thorium can also be used as a fuel in nuclear reactors.

However, Th itself was not fissile, it convert into the fissile isotope U-233 onto absorption of a neutron. Thorium is mostly a health hazard only if it uses into the body. External gamma disclosure was not a great concern because thorium emits only a small quantity of gamma radiation (<http://hpschapters.org/northcarolina/NSDS/thorium.pdf>). In this study, the thoriom element using for $p + {}_{90}\text{Th}^{232}$ Reaction formation by CEM03 program.

In that reactions, at different energies the double differential cross section with the all forms cross section with the same mass number were calculated also thoughtful that result by CEM03 program and compared so as to result with experimentally measured values.

4.3.1.1. Alpha Double Differential Cross Section for $p + {}_{90}\text{Th}^{232}$ Reaction at $E_p=20$ MeV; $\theta=60^\circ$

The double differential cross sections $d^2\sigma/dE.d\theta$ of emission (alpha, neutron and proton) particle for $p + {}_{90}\text{Th}^{232}$ reactions are calculated by CEM03 code program.

The calculate double differential cross section $d^2\sigma/dE.d\theta$ of alpha emission for $p + {}_{90}\text{Th}^{232}$ at 20 MeV incident energetic protons are illustrative in the Figure and Table 4.1., respectively. The shape of calculate results curve of double differential cross section ($d^2\sigma/dE.d\theta$) for alpha emission at this energy for four steps (Total, Cascade, Precompound and Evaporation) are different at angle 60° . The form of calculate results curve are nearly similar to total and precompound.

On the other hand, the evaporation increases together with increases alpha energies emission. However, the cascade in this case not shown because, all results are zero, the incident proton energy is smaller to target element, has large mass number.

Additionally, number of elastic interactions and number of inelastic interactions are (341590 and 1000000), respectively. While, reaction cross section and elastic cross section are about (1477.87 and 504.82 mb), respectively.

4.3.1.2. Alpha Double Differential Cross Section for $p + {}_{90}\text{Th}^{232}$ Reaction at $E_p=20$ MeV; $\theta=60^\circ$, Compare between CEM03 and Experimental Data

Figure 4.2. Shows that the comparison of calculated double differential cross section of alpha emission with experimental data at the incident proton energy 20 MeV with angle 60° degree. For $^{232}\text{Th}(p, \alpha)$ reaction the pre-equilibrium calculations (cascade- exciton CEM03 and hybrid models) are in good agreement with the measurements. However, the experimental data and CEM03 have an inconsistency at energies 20 MeV Figure 4.2.

Also, the highest value in CEM03 code program is 0.008 at 24 MeV but in experimental data the highest value is 0.089 at 25.511 MeV. However, the lowest value in CEM03 code program is recording as 0.001 at 22 MeV but in experimental data the lowest value is about 0.001 at 29.953 MeV.

4.3.1.3. Alpha Double Differential Cross Section for $p + {}_{90}\text{Th}^{232}$ Reaction at $E_p=360$ MeV; $\theta=22^\circ$

The double differential cross sections $d^2\sigma/dE.d\theta$ of emission (alpha, neutron and proton) particle for $p + {}_{90}\text{Th}^{232}$ reactions are calculated by CEM03 code program. The calculate double differential cross section $d^2\sigma/dE.d\theta$ of alpha emission for $p + {}_{90}\text{Th}^{232}$ at 360 MeV incident energetic protons are illustrative in Figure 4.3 and Table 4.3. The results are showing different shapes of curve of the double differential cross section ($d^2\sigma/dE.d\theta$) for alpha emission at this energy for four steps (Total, Cascade, Precompound and Evaporation) at angle 22° . As can be seen in Figure 4.3 total double differential cross section with evaporation is increasing when alpha energies are increasing until the peak, after that each others are decreasing slightly when alpha energies are increasing. On the other hand, the cascade at the beginning of a graphic form is increasing with increasing of the alpha energy to reach the highest point. After it increases and decreases alternately with increasing alpha energy emitted.

Similarly, precompound is increasing by increasing of the alpha energy to reach the highest point after it, increases and decreases alternately with increasing alpha energy emitted. In addition, number of elastic interactions is 578028, number of inelastic interactions is 1000000, Reaction cross section is 1728.55 mb and elastic cross section is 999.15 mb.

4.3.1.4. Alpha Double Differential Cross Section for $p + {}_{90}\text{Th}^{232}$ Reaction at $E_p=360$ MeV; $\theta=22^\circ$, Compare between CEM03 and Experimental Data

The comparison of calculate double differential cross section of alpha emission with experimental data at the incident proton energy 360 MeV with angle 22° degree are given in Figure 4.4 and Table 4.4. For $^{232}\text{Th}(p, x\alpha)$ reaction the pre-equilibrium calculations (cascade- exciton CEM03 and hybrid models) in good agreement with the measurements. However, the calculate results are also in good agreement with experimental data at energies 360 MeV Figure 4.4.

In addition, the highest value in CEM03 code program is 1.968 at 24 MeV but in experimental data the highest value is 1.39 at 110.9 MeV. However, the lowest value in CEM03 code program is 0.003 at 90MeV while in experimental data the lowest value is 0.81 at 239.1 MeV.

4.3.1.5. Alpha Double Differential Cross Section for $p + {}_{90}\text{Th}^{232}$ Reaction at $E_p=500$ MeV; $\theta=40^\circ$

The double differential cross sections $d^2\sigma/dE.d\theta$ of emission (alpha, neutron and proton) particle for $p + {}_{90}\text{Th}^{232}$ reactions are calculated by CEM03 code program.

The calculate double differential cross section $d^2\sigma/dE.d\theta$ of alpha emission for $p + {}_{90}\text{Th}^{232}$ at 500 MeV incident energetic protons are showing in Figure 4.5 and Table 4.5. The shape of calculate results curve of double differential cross section ($d^2\sigma/dE.d\theta$) for alpha emission at this energy for four steps (Total, Cascade, Precompound and Evaporation) are different at angle 40° . As can be seen in Figure 4.5 total cross section and evaporation are increasing at beginning when alpha energy is increasing until the peak, after that, evaporation is decreasing slightly when alpha energy is increasing but total cross section is decreasing normally. On the other hand, when cascade and precompound at begin in a graphic form are increasing sharply with increasing of the alpha energy to reach the highest point at the peak, while they are decreases slope form with increasing alpha energy emitted. In addition, number of elastic interactions is 529193, number of inelastic in-

teractions is 1000000, reaction cross section is 1746.35 mb and elastic cross section is 924.16 mb.

4.3.1.6. Alpha Double Differential Cross Section for $p + {}_{90}\text{Th}^{232}$ Reaction at $E_p=500$ MeV; $\theta=40^\circ$, Compare between CEM03 and Experimental Data

The comparison of calculate double differential cross section of alpha emission with experimental data at the incident proton energy 500 MeV with angle 40° degree are showing in Figure 4.6 and the Table 4.6. For $^{232}\text{Th}(p, \alpha)$ reaction the pre-equilibrium calculations (cascade- exciton CEM03 and hybrid models) are in good agreement with the measurements. From Figure 4.6, the calculate results are also in good agreement with experimental data at energies 500 MeV.

The highest value in CEM03 code program is 3.698 at 24 MeV but in experimental data the highest value is 0.83 at 118.2 ,128.5 and 137.5 MeV respectively. However, the lowest value in CEM03 code program is recording at 0.013 at 1MeV while in experimental data the lowest value is 0.0183 at 388.5 MeV.

Figure 4.6. Double Differential Cross Section (mb/MeV.sr) of the alphas generated as a result of bombardment of element $_{90}\text{Th}^{232}$ with 500 MeV energetic protons and $\theta=40^\circ$ degree

4.3.1.7. Alpha Double Differential Cross Section for $p + {}_{90}\text{Th}^{232}$ Reaction at $E_p=500$ MeV; $\theta=70^\circ$

The double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p + {}_{90}\text{Th}^{232}$ reactions are calculated by CEM03 code program. The calculate double differential cross section ($d^2\sigma/dE.d\theta$) of alpha emission for $p + {}_{90}\text{Th}^{232}$ at 500 MeV incident energetic protons are illustrative in Figure 4.7 and Table 4.7. The shape of calculate results curve of double differential cross section ($d^2\sigma/dE.d\theta$) for alpha emission at this energy for four steps (Total, Cascade, Precompound and Evaporation) are different at angle 70° . The form of calculate results curve are nearly similar to total and evaporation because, both have one peak but evaporation decreases slightly when alpha energy increases. On the other hand, cascade and precompound double differential cross section are increasing with increasing alpha energies emission, it is to reach the highest value , then they both decreases in a slope form when increases alpha energy.

Moreover, number of elastic interactions and number of inelastic interactions are recorded about (529193 and 1000000), separately. However, the reaction cross section is 1746.35 mb and elastic cross section is 924.16 mb.

4.3.1.8. Alpha Double Differential Cross Section for $p + {}_{90}\text{Th}^{232}$ Reaction at $E_p=500$ MeV; $\theta=70^\circ$, Compare between CEM03 and Experimental Data

The comparison of calculate double differential cross section of alpha emission with experimental data at the incident proton energy 500 MeV with angle 70° degree. For $^{232}\text{Th}(p, \alpha)$ reaction the pre-equilibrium calculations (cascade- exciton CEM03 and hybrid models) are in good agreement with the measurements. Results from Figure 4.8 are also shows that the calculate in good agreement with experimental data at energies 500 MeV. The highest value in CEM03 code program is 3.622 at 24 MeV but in experimental data the highest value is 0.66 at 52 MeV. However, the lowest value in CEM03 code program is 0.007 at 1 MeV but in experimental data the lowest value is 0.005 at 269 MeV.

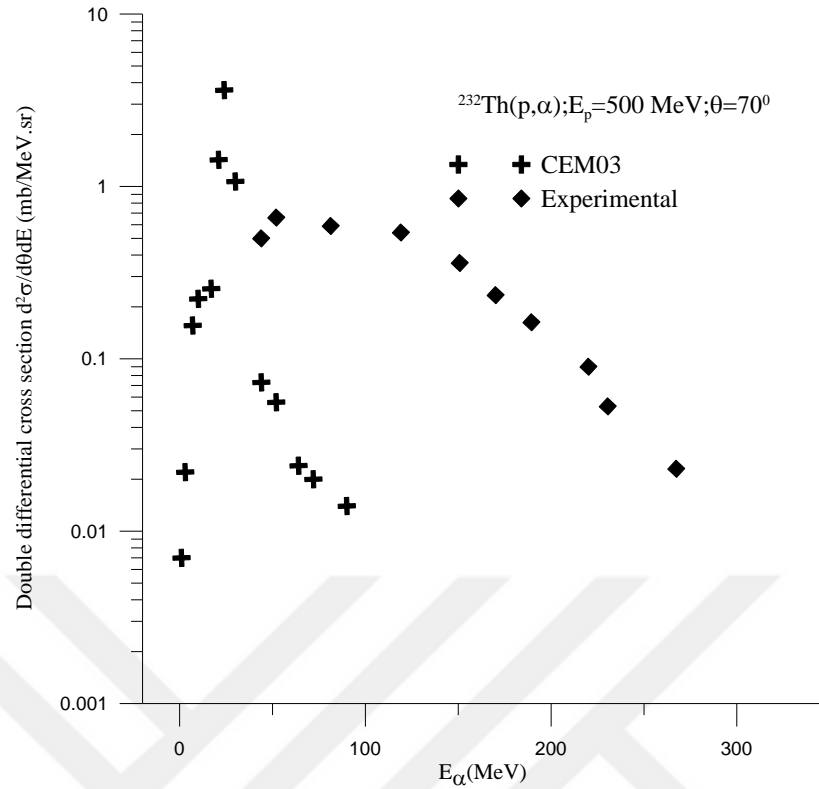

Figure 4.8. Double differential cross section (mb/MeV.sr) of the alphas generated as a result of bombardment of element ${}_{90}\text{Th}^{232}$ with 500 MeV energetic protons and $\theta = 70^\circ$ degree

4.3.1.9. Alpha Double Differential Cross Section for $p + {}_{90}\text{Th}^{232}$ Reaction at $E_p=360$ MeV; $\theta = (0^\circ, 20^\circ, 40^\circ, 60^\circ)$

The double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p + {}_{90}\text{Th}^{232}$ reactions are calculated by CEM03 code program. The calculate consequences of the double differential cross sections ($d^2\sigma/dE.d\theta$) of alpha particle emission for $p + {}_{90}\text{Th}^{232}$ reaction are illustrative in Figure 4.9 and Table 4.9, at the proton incident energy 360 MeV. The calculation of total double differential cross section are various for angles ($0^\circ, 20^\circ, 40^\circ$ and 60°). The form of calculated results curve are similar to each other. The peaks of the curves at high alpha emission energy are participates of the immediate reaction mechanism. From the line graph, total double differential cross section are decreasing in a different orientation, because of various angles. In addition, number of elastic interactions is 578028, number of inelastic interactions is 1000000, reaction cross section is 1728.55 mb and elastic cross section is 999.15 mb.

Table 4.9. Alpha scattered Double differential cross section (mb/MeV.Sr) for $p + {}_{90}\text{Th}^{232}$ reaction , $E_p=360$ MeV energy with $\theta= (0^{\circ}, 20^{\circ}, 40^{\circ}, 60^{\circ})$ degree Calculation have been made by CEM03 code program

Figure 4.9. Double differential cross section (mb/MeV.sr) of the alphas generated as a result of bombardment of element ${}_{90}\text{Th}^{232}$ with 360 MeV energetic protons and $\theta = (0^\circ, 20^\circ, 40^\circ, 60^\circ)$ degree respectively

4.3.1.10. Neutron Double Differential Cross Section for $p + {}_{90}\text{Th}^{232}$ Reaction at $E_p=360$ MeV; $\theta = (0^\circ, 20^\circ, 40^\circ, 60^\circ)$

The double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p + {}_{90}\text{Th}^{232}$ reactions are calculated by CEM03 code program. The calculate consequences of the double differential cross sections ($d^2\sigma/dE.d\theta$) of neutron particle emission for $p + {}_{90}\text{Th}^{232}$ reaction are illustrative in Figure 4.10 and Table 4.10, at the proton incident energy 360 MeV. The calculate results are at angles $0^\circ, 20^\circ, 40^\circ$ and 60° that results for total double differential cross section are various for different angles. At the beginning of the curves, total double differential cross section for different angles are decreasing with increasing neutron energy emission. The form of calculated results curve are similar to each other, until amount energy above 100 MeV after that values of total double differential cross section are various. From the line graph, total double differential cross section is not change, for 0° and 20° degree but on top of 300 MeV, total double differential for 0° degree is increasing with increasing neutron energy emission. However, for 20° degree was counteracted.

On the other hand, for 40° and 60° degree over 100 MeV the total differential are decreasing gradually when neutron energy emission are increasing. In addition, number of elastic interactions is 578028, number of inelastic interactions is 1000000, reaction cross section is 1728.55 mb and elastic cross section is 999.15 mb.

Figure 4.10. Double differential cross section (mb/MeV.sr) of the neutron generated as a result of bombardment of element $_{90}\text{Th}^{232}$ with 360 MeV energetic protons and $\theta=(0^\circ, 20^\circ, 40^\circ, 60^\circ)$ degree respectively

4.3.1.11. Proton Double Differential Cross Section for $p + {}_{90}\text{Th}^{232}$ Reaction at $E_p=360$ MeV; $\theta= (0^0, 20^0, 40^0, 60^0)$

CEM03 code program was applied to calculation the double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p + {}_{90}\text{Th}^{232}$ reactions.

The calculate consequences of $d^2\sigma/dE.d\theta$ of proton particle emission for $p + {}_{90}\text{Th}^{232}$ reaction are illustrative in Figure 4.11 and Table 4.11, at the proton incident energy 360 MeV.

The calculate results are at angles 0^0 , 20^0 , 40^0 and 60^0 that results for total double differential cross section are various for different angles. At the beginning of the curves, total double differential cross section for different angles are increasing sharply when proton energy emission is increasing. The peaks of the curves at high proton emission energy are participates of the immediate reaction mechanism.

The form of calculate results curve are similar to each other, they are decreasing while amount energy bring to above 100 MeV except 40^0 and 60^0 degree, after that accounts of total double differential cross section are various. From the graph, total double differential cross section on 100 MeV is not change until the quantity almost bring to 300 MeV for 0^0 degree, but after this value it is increasing.

However, subsequent to the peak, total differential cross section for 20^0 degree is decreasing until amount nearly bring to 200 MeV, after this amount increases and decreases alternately.

In addition, number of elastic interactions is 578028, number of inelastic interactions is 1000000, reaction cross section is 1728.55 mb and elastic cross section is 999.15 mb.

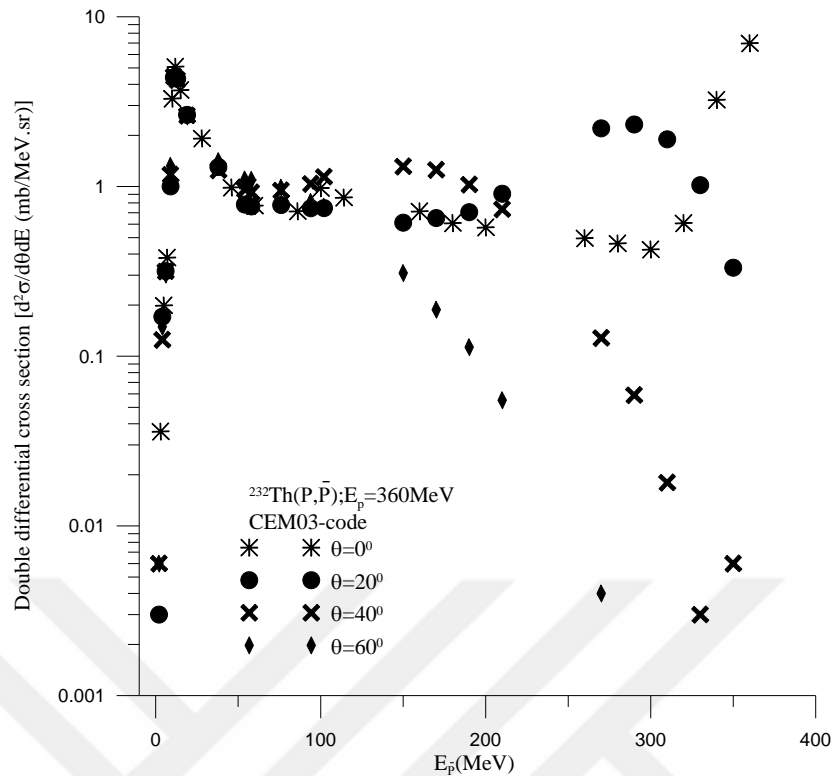

Figure 4.11. Double differential cross section (mb/MeV.sr) of the proton generated as a result of bombardment of element ${}_{90}\text{Th}^{232}$ with 360 MeV energetic protons and $\theta = (0^\circ, 20^\circ, 40^\circ, 60^\circ)$ degree respectively

4.3.2. $p + {}_5\text{B}^{10}$ Reaction

4.3.2.1. Neutron Double Differential Cross Section for $p + {}_5\text{B}^{10}$ Reaction at $E_p = 30$ MeV; $\theta = 2^\circ$

The double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p + {}_5\text{B}^{10}$ reactions are calculated by CEM03 code program. The calculate double differential cross section ($d^2\sigma/dE.d\theta$) of neutron emission for $p + {}_5\text{B}^{10}$ at 30 MeV incident energetic proton are illustrative in Figure 4.12 and Table 4.12.

The form of calculate results curve of double differential cross section ($d^2\sigma/dE.d\theta$) for neutron emission at this energy for four steps (Total, Cascade, Precompound and Evaporation) are different at angle 2° degree. At the begin total double differential cross section decreasing with increasing neutron energy emission until above 5 MeV.

After that this value is increasing gradually with increasing neutron energy emission as can be seen in Figure 4.12. For cascades, increases steadily when increases neutron energy emission until bring to the highest point, although increases with increases energy emission. On the other hand, evaporation is decreasing when neutron energies are increasing. However, the precompound in this case not shown in this line graph because all results are zero, the incident proton energy is bigger than target element, has small mass number.

In addition, number of elastic interactions is 1398484, number of inelastic interactions is 1000000, reaction cross section is 445.68 mb, elastic cross section is 623.28 mb.

4.3.2.2. Neutron Double Differential Cross Section for $p + ^{10}\text{B}$ Reaction at $E_p=30$ MeV; $\theta=2^\circ$, Compare between CEM03 and Experimental Data

The comparison of calculate double differential cross section of neutron emission with experimental data at the incident proton energy 30 MeV with angle 2° degree are showing in Figure 4.13 and Table 4.13. For $^{10}\text{B}(p, xn)$ reaction the pre-equilibrium calculations (cascade- exciton CEM03 and hybrid models) are in good agreement with the measurements. From Figure 13, the experimental data and CEM03 data have an inconsistency at energies 16 MeV. In addition, both the CEM03 data and experimental data results are decreasing at energies 25 MeV .

Figure 4.13. Double differential cross section (mb/MeV.sr) of the Neutron generated as a result of bombardment of element ${}^5\text{B}^{10}$ with 30 MeV energetic protons and $\theta=20$ degree

4.3.2.3. Neutron Double Differential Cross Section for $p + {}^5\text{B}^{10}$ Reaction at $E_p=50$ MeV; $\theta=30^\circ$

The $d^2\sigma/dE.d\theta$ of emission (alpha, neutron and proton) particle for $p + {}^5\text{B}^{10}$ reactions are calculated by CEM03 code program. The calculate $d^2\sigma/dE.d\theta$ of neutron emission for $p + {}^5\text{B}^{10}$ at 50 MeV incident energetic protonis shown in Figure 4.14 and Table 4.14. The shape of calculate results curve of $d^2\sigma/dE.d\theta$ for neutron emission at this energy for four steps (Total, Cascade, Precompound and Evaporation) are different at angle 30° degree. As can be seen in Figure 4.14 at the beginning of the curve, total double differential cross section decreasing when neutron energy emission bring to 20 MeV. Neutron energy emission at value of 20 MeV is caused to decrease total double differential cross section as can be seen in Figure 4.14. After that value is not change although, where as neutron energy emission almost bring to 36 MeV, then it is descend once more. From the line graph, cascade double differential cross section is increasing slowly together with increasing neutron energy emission. On the other hand, evaporation is descend dramatically when neutron energies are increasing.

However, the precompound in this case not shown in this line graph because, all results are zero, the incident proton energy is bigger than target element, has small mass number. In addition, number of elastic interactions is 1755733, number of inelastic interactions is 1000000, reaction cross section is 342.84 mb, elastic cross section is 601.94 mb.

Figure 4.15. Double differential cross section (mb/MeV.sr) of the Neutron generated as a result of bombardment of element ${}^5\text{B}^{10}$ with 50 MeV energetic protons and $\theta=30^\circ$ degree

4.3.2.5. Neutron Double Differential Cross Section for $p+{}^5\text{B}^{10}$ Reaction at $E_p=186$ MeV; $\theta=0^\circ$

CEM03 code program is also used to determination the double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p+{}^5\text{B}^{10}$ reactions.

Figure 4.16 and Table 4.16 are showing the results of double differential cross section ($d^2\sigma/dE.d\theta$) of neutron emission for $p+{}^5\text{B}^{10}$ at 186 MeV incident energetic proton. Different shapes are recording at angle 0° degree of double differential cross section $d^2\sigma/dE.d\theta$ for neutron emission at this energy for four steps (Total, Cascade, Precompound and Evaporation).

It shows that at the beginning of the curve, total and cascade double differential cross section are decreasing a little more when neutron energy emission is increasing. On the other hand, evaporation is decreasing gradually with increasing neutron energies. However, the results of precompound in this case are not showing in the line graph because,

all results are zero. The incident proton energy is bigger than target element, has small mass number. In addition, number of elastic interactions and number of inelastic interactions are about (2991607 and 1000000), respectively. Furthermore, (189.34 and 566.43 mb) are recorded as reaction cross section and elastic cross section, respectively.

4.3.2.6. Neutron Double Differential Cross Section for $p + ^{10}\text{B}$ Reaction at $E_p=186$ MeV; $\theta=0^\circ$, Compare between CEM03 and Experimental Data

The comparison of calculate double differential cross section of neutron emission with experimental data at the incident proton energy 186 MeV with angle 0° degree are showing in Figure 4.17 and Table 4.17. For $^{10}\text{B}(p, xn)$ reaction the pre-equilibrium calculations (cascade- exciton CEM03 and hybrid models) are in good agreement with the measurements. From Figure 4.17, the CEM03 and experimental data have about inconsistency at energies 20 MeV.

Additionally, in the result for both the experimental and CEM03 are decreasing at energies 10 MeV.

Figure 4.17. Double differential cross section (mb/MeV.sr) of the Neutron generated as a result of bombardment of element ${}^5\text{B}^{10}$ with 186 MeV energetic protons and $\theta=0^\circ$ degree

4.3.2.7. Neutron Double Differential Cross Section for $p + {}^5\text{B}^{10}$ Reaction at $E_p=186$ MeV; $\theta=20^\circ$

The double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p + {}^5\text{B}^{10}$ reactions are calculated by CEM03 code program. The calculate double differential cross section ($d^2\sigma/dE.d\theta$) of neutron emission for $p + {}^5\text{B}^{10}$ at 186 MeV incident energetic proton illustrative in Figure 4.18 and Table 4.18. The shape of calculate results curve of double differential cross section $d^2\sigma/dE.d\theta$ for neutron emission at this energy for four steps (Total, Cascade, Precompound and Evaporation) are different at angle 20° degree. It shows that at the beginning of the curve until up to 30 MeV, total and cascade double differential cross section decreasing a little more when neutron energy emission is increasing. After that amount, they are almost steady as the neutron emission energy increases. On the other hand, evaporation is a gradual decreasing when neutron energies are increasing. However, the precompound in this case is not showing in the line graph since all results are zero. The incident proton energy is bigger than target element, it has small mass number.

In addition, number of elastic interactions is 2991607, number of inelastic interactions is 1000000, reaction cross section is 189.34 mb, elastic cross section is 566.43 mb.

Figure 4.18. Double differential cross section (mb/MeV.sr) of the Neutron generated as a result of bombardment of element ^{10}B with 186 MeV energetic protons and $\theta=20^\circ$ degree

4.3.2.8. Neutron Double Differential Cross Section for $p + ^{10}\text{B}$ Reaction at $E_p=186$ MeV; $\theta=20^\circ$, Compare between CEM03 and Experimental Data

The comparison of calculate double differential cross section of neutron emission with experimental data at the incident proton energy 186 MeV with angle 20° degree are demonstrated in Figure 4.19 and Table 4.19. For $^{10}\text{B}(p, xn)$ reaction the pre-equilibrium calculations (cascade- exciton CEM03 and hybrid models) are in good agreement with the measurements.

From Figure 4.19, the experimental and CEM03 data have about an inconsistency at energies 20 MeV. In addition, both the CEM03 and experimental data results are decreasing at energies 88 MeV.

Figure 4.19. Double differential cross section (mb/MeV.sr) of the Neutron generated as a result of bombardment of element ${}^5\text{B}^{10}$ with 186 MeV energetic protons and $\theta = 20^\circ$ degree

4.3.2.9. Neutron Double Differential Cross Section for $p + {}^5\text{B}^{10}$ Reaction at $E_p = 186$ MeV; $\theta = 44^\circ$

The double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p + {}^5\text{B}^{10}$ reactions are calculated by CEM03 code program. Figure 4.20 and Table 4.20, are showing the results of double differential cross section ($d^2\sigma/dE.d\theta$) of neutron emission for $p + {}^5\text{B}^{10}$ at 186 MeV incident energetic proton. Different results are found of double differential cross section $d^2\sigma/dE.d\theta$ for neutron emission at this energy for four steps (Total, Cascade, Precompound and Evaporation) at angle 44° degree.

It is shows that total and cascade double differential cross section are decreasing with increasing the neutron energy emission at the beginning of the curve until up to 40 MeV, after that amount, they are almost steady as the neutron emission energy increases. On the other hand, evaporation is a gradual decreasing when neutron energies are increasing. However, in the results of the line graph any point is not recorde for the precompound, the incident proton energy is bigger than target element, has small mass number.

Besides that, number of elastic interactions and number of inelastic interactions are about (2991607 and 1000000), respectively. Also, reaction cross section and elastic cross section are recorded by (189.34 and 566.43 mb), respectively.

4.3.2.10. Neutron Double Differential Cross Section for $p + ^{10}\text{B}$ Reaction at $E_p = 186$ MeV; $\theta = 44^\circ$, Compare between CEM03 and Experimental Data

The comparison of calculate double differential cross section of neutron emission with experimental data at the incident proton energy 186 MeV with angle 44° degree are showing in Figure and Table 4.21. For $^{10}\text{B}(p, xn)$ reaction the pre-equilibrium calculations (cascade- exciton CEM03 and hybrid models) are in good agreement with the measurements. From Figure 4.21, the experimental and CEM03 data have an inconsistency at energies 90 MeV.

In addition, CEM03 data at the beginning of the curve are decreasing with increasing energies. However, experimental data is increasing.

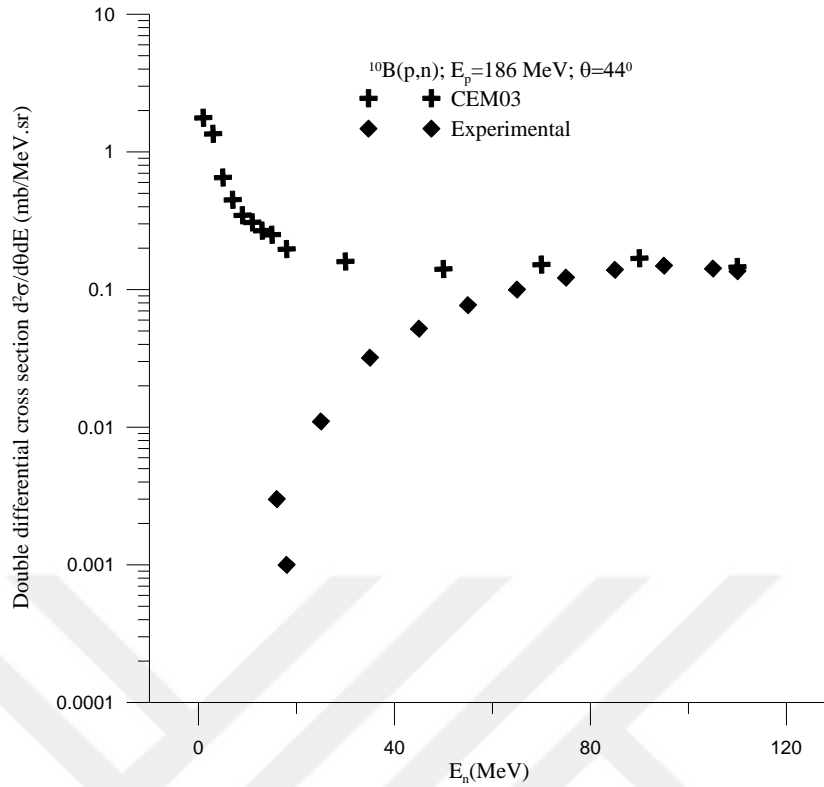

Figure 4.21. Double differential cross section (mb/MeV.sr) of the Neutron generated as a result of bombardment of element ${}^5\text{B}^{10}$ with 186 MeV energetic protons and $\theta=44^\circ$ degree

4.3.2.11. Neutron Double Differential Cross Section for $p + {}^5\text{B}^{10}$ Reaction at $E_p=186$ MeV; $\theta=49^\circ$

CEM03 code program is applied for calculation the double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p + {}^5\text{B}^{10}$ reactions. The calculate double differential cross section ($d^2\sigma/dE.d\theta$) of neutron emission for $p + {}^5\text{B}^{10}$ at 186 MeV incident energetic proton are showing in Figure 4.22 and Table 4.22. The shape of calculate results curve of double differential cross section $d^2\sigma/dE.d\theta$ for neutron emission at this energy for four steps (Total, Cascade, Precompound and Evaporation) are different at angle 49° degree. It shows that at the beginning of the curve, total and cascade double differential cross section are decreasing when neutron energy emission is increasing. After that, they are almost steady as the neutron emission energy increases. On the other hand, evaporation is a gradual decreasing when neutron energies are increasing. However, the precompound in this case is not showing in the line graph because, all results are zero, the incident proton energy is bigger than target element, has small mass number. In addition, at energy 186 MeV with angles (0° , 20° , 44° and 49°) degree almost

comparable to the amount especially at angles 44° and 49° because the values of those angles are tiny. Number of elastic interactions is 2991607, number of inelastic interactions is 1000000, reaction cross section is 189.34 mb, elastic cross section is 566.43 mb.

4.3.2.12. Neutron Double Differential Cross Section for $p + ^{10}\text{B}$ Reaction at $E_p=186$ MeV; $\theta=49^\circ$, Compare between CEM03 and Experimental Data

Figure 4.23 and Table 4.23, are showing the comparison of calculate double differential cross section of neutron emission with experimental data at the incident proton energy 186 MeV with angle 49° degree. For $^{10}\text{B}(p, xn)$ reaction the pre-equilibrium calculations (cascade- exciton CEM03 and hybrid models) are in good agreement with the measurements. The experimental and CEM03 data have an inconsistency at energies 70 MeV.

In addition, CEM03 data at the beginning of the curve are decreasing with increasing energies. However, experimental data is increasing.

4.3.2.13. Alpha Double Differential Cross Section for $p + {}^5\text{B}^{10}$ Reaction at $E_p= 660$ MeV; $\theta= 90^\circ$

The double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p + {}^5\text{B}^{10}$ reactions are calculated by CEM03 code program. The calculate double differential cross section $d^2\sigma/dE.d\theta$ of alpha emission for $p + {}^5\text{B}^{10}$ at 660 MeV incident energetic proton illustrative in Figure 4.24 and Table 4.24. The form of calculate results curve of double differential cross section ($d^2\sigma/dE.d\theta$) for alpha emission at this energy for four steps (Total , Cascade , Precompound and Evaporation) are different at angle 90° degree. From the line graph, total and evaporation double differential cross section gradually decreasing when alpha energy emission is increasing. Although, cascade double differential cross section is increasing and decreasing alternately slowly together with increasing alpha energy emission. On the other hand, the precompound in this case is not showing in this graph since, all results are zero, the incident proton energy is bigger than target element, has small mass number.

In addition, number of elastic interactions is by 2311831, number of inelastic interactions is 1000000, reaction cross section is 215.50 mb, elastic cross section is about 498.21 mb.

Table 4.24. Alpha Scattered Double Differential Cross Section (mb/MeV.sr) for p + ${}^5\text{B}^{10}$ reaction, $E_p=660$ MeV energy with $\theta=90^\circ$ degree Calculation have been made by CEM03 code program

Figure 4.24. Double differential cross section (mb/MeV.sr) of the Alpha generated as a result of bombardment of element ^{10}B with 660 MeV energetic protons and $\theta=90^\circ$ degree

4.3.2.14. Alpha Double Differential Cross Section for $p + ^{10}\text{B}$ Reaction at $E_p=660$ MeV; $\theta=90^\circ$, Compare between CEM03 and Experimental Data

The comparison of calculate double differential cross section of alpha emission with experimental data at the incident proton energy 660 MeV with angle 90° degree are showing in Figure 4.25 and Table 4.25.

For $^{10}\text{B}(p, \alpha)$ reaction the pre-equilibrium calculations (cascade- exciton CEM03 and hybrid models) are in good agreement with the measurements. The CEM03 and experimental data have an inconsistency at energies 10 MeV. Additionally, both the experimental and CEM03 data results are decreasing.

Figure 4.25. Double differential cross section (mb/MeV.sr) of the alpha generated as a result of bombardment of element ${}^5\text{B}^{10}$ with 660 MeV energetic protons and $\theta=90^\circ$ degree

4.3.2.15. Alpha Double Differential Cross Section for $p + {}^5\text{B}^{10}$ Reaction at $E_p=186$ MeV; $\theta= (0^\circ, 20^\circ, 40^\circ, 60^\circ)$

CEM03 code program is used to calculation of the double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p + {}^5\text{B}^{10}$ reactions. The calculate outcome of the double differential cross sections ($d^2\sigma/dE.d\theta$) of alpha particle emission for $p + {}^5\text{B}^{10}$ reaction at the proton incident energy 186 MeV are showing in Figure 4.26 and (Table 4.26).

The calculate results are at angles 0° , 20° , 40° and 60° that results for total double differential cross section are various for different angles. At the beginning of the curves, total double differential cross section for different angles are decreasing gradually together with increasing alpha energy emission. The form of calculate results curve are similar to each others. However, when alpha energy emission is increasing the total double differential cross section is separate, since they are various at angles.

On the other hand, total double differential cross section for (0^0) degree is different to others because at the end of energy emission is increasing when alpha energy emission is increasing. In addition, number of elastic interactions is 2980182, number of inelastic interactions is 1000000, reaction cross section is 189.98 mb and elastic cross section is 566.18 mb.

Table 4.26. Alpha Scattered Double Differential Cross Section (mb/MeV.sr) for $p + {}_5\text{B}^{10}$ reaction, $E_p=186$ MeV energy with $\theta= (0^0, 20^0, 40^0, 60^0)$ degree Calculation have been made by CEM03 code program

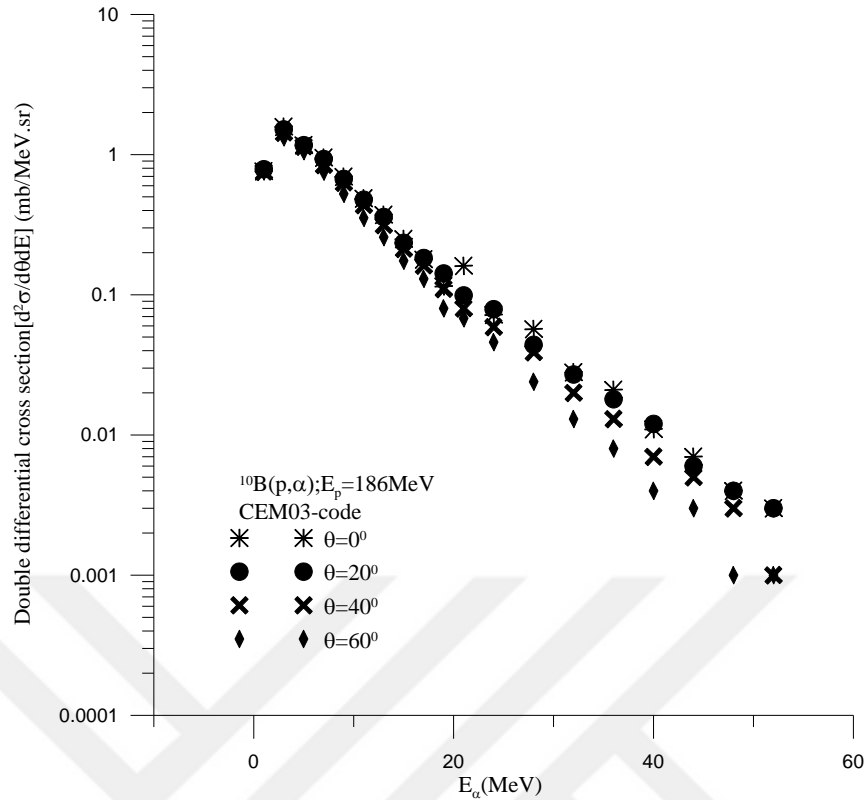

Figure 4.26. Double differential cross section (mb/MeV.sr) of the alpha generated as a result of bombardment of element ${}^5\text{B}^{10}$ with 186 MeV energetic protons and $\theta = (0^\circ, 20^\circ, 40^\circ, 60^\circ)$ degree respectively

4.3.2.16. Neutron Double Differential Cross Section for $\text{p} + {}^5\text{B}^{10}$ Reaction at $E_p = 186$ MeV; $\theta = (0^\circ, 20^\circ, 40^\circ, 60^\circ)$

The double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $\text{p} + {}^5\text{B}^{10}$ reactions are calculated by CEM03 code program. The calculate product of the double differential cross sections ($d^2\sigma/dE.d\theta$) of neutron particle emission for $\text{p} + {}^5\text{B}^{10}$ reaction are showing in Figure and Table 4.27, at the proton incident energy 186 MeV. Different results are recording for total double differential cross section at angles $0^\circ, 20^\circ, 40^\circ$ and 60° . At the beginning of the curves, total double differential cross section for different angles are decreasing sharply when is neutron energy emission increasing. The form of calculate results curve are similar to each other, they are decreasing while amount energy bring to above 40 MeV except 40° and 60° degree, after that accounts of total double differential cross section are various. From the graph, total double differential cross section on 40 MeV is not change until the quantity almost bring to 160 MeV for 0° degree, but after this value which is increasing.

However, total double differential cross section for 20° degree is increasing until amount nearly bring to top of 160 MeV, after that which is decreasing with increasing neutron energy emission. In addition, number of elastic interactions is 2980182, number of inelastic interactions is 1000000, reaction cross section is 189.98 mb and elastic cross section is 566.18 mb.

Figure 4.27. Double differential cross section (mb/MeV.sr) of the neutron generated as a result of bombardment of element ^{10}B with 186 MeV energetic protons and $\theta = (0^\circ, 20^\circ, 40^\circ, 60^\circ)$ degree respectively

4.3.2.17. Proton Double Differential Cross Section for $p + ^{10}\text{B}$ Reaction at $E_p = 186$ MeV; $\theta = (0^\circ, 20^\circ, 40^\circ, 60^\circ)$

CEM03 code program is used to calculation of the double differential cross sections ($d^2\sigma/dE.d\theta$) of emission (alpha, neutron and proton) particle for $p + ^{10}\text{B}$ reactions.

The calculate consequences of the double differential cross sections ($d^2\sigma/dE.d\theta$) of proton particle emission for $p + ^{10}\text{B}$ reaction at the proton incident energy 186 MeV are showing in Figure 4.28 and Table 4.28. The calculate results at angles $0^\circ, 20^\circ, 40^\circ$ and 60° for total double differential cross section are various for different angles. At the beginning of the curves, total double differential cross section for different angles are increasing sharply when proton energy emission is increasing. The peaks of the curves at high proton emission energy are participating of the immediate reaction mechanism. The form of calculate results curve are similar to each others. Total double differential cross section are decreasing when amount of energy bring to 40 MeV, after that accounts of total double differential cross section are various.

From the graph, total double differential cross section on 40 MeV is increasing until the quantity almost bring to 90 MeV for 40⁰ degree, but after this value it is decreasing. However, subsequent to the peak, total differential cross section for 60⁰ degree is decreasing with increasing proton energy emission.

On the other hand, for 20⁰ degree behind the highest point of total double differential cross section is decreasing when is proton energy emission increasing until amount nearly bring to 72 MeV, after that which is increasing dramatically while proton energy emission bring to 160 MeV. Then, it is decreasing once more. As well as, for 0⁰ degree total double differential is not change until bring to 160 MeV, after that value is increasing sharply when proton energy emission is increasing. In addition, number of elastic interactions is 2980182, number of inelastic interactions is 1000000, reaction cross section is 189.98 mb and elastic cross section is 566.18 mb.

Figure 4.28. Double differential cross section (mb/MeV.sr) of the proton generated as a result of bombardment of element ^{10}B with 186 MeV energetic protons and $\theta = (0^\circ, 20^\circ, 40^\circ, 60^\circ)$ degree respectively

5. CONCLUSION

In this study, nuclear theory models are applied to calculate $d^2\sigma/dE.d\theta$ for (p, $x\alpha$), (p, xn) and (p, xp) reactions on ^{232}Th and ^{10}B target nuclei which have been measured for (20 to 660) MeV incident proton energy ranges by using CEM03.1 codes. The results are compared with the published experimental data.

In this research, $d^2\sigma/dE.d\theta$ are calculated on a several targets at different energies. Also, the incident proton energies are used randomly, for instance 20 MeV, 500 MeV and 186 MeV for Thorium and Boron elements, because the experimental data bank in internet website Nuclear Energy Agency (NEA) has this incident energy ranges.

The computational results on $d^2\sigma/dE.d\theta$ for reactions process are given in Tables and Figures (1 to 28), the theoretical model computations apply for reactions are in good agreement with the experimental data. Generally the theoretical models including intra-nuclear cascade (INC) model, pre-equilibrium and equilibrium reaction theories prepared the good attributive of the Figures and importance of the $d^2\sigma/dE.d\theta$ of alpha particle, neutron and proton emissions. Therefore, we used proton energy induced in nuclear reaction for $d^2\sigma/dE.d\theta$ data which are very essential for more than a few practical applications. In this research, especially calculation results has several errors because the program do not reproduce the output or consequence at occasionally, CEM03.1 program that has a specially method.

In the CEM03.1 program code results for $p + {}_{90}\text{Th}^{232}$ interaction and particles (α , n, p) are calculated, respectively. As a result in this code for $p + {}_{90}\text{Th}^{232}$ at $E_p=(20, 360, 500, 500)$ MeV at angles $\theta= (60.25^\circ, 20^\circ, 40^\circ, 70^\circ)$ in that order, in this reactions alpha (α) emitted has been made for four steps (Total, Cascade, Precompound, Evaporation). For all results in Figures (4.1, 4.2, 4.3, 4.4) at the beginning of the curves indicates double differential cross section $d^2\sigma/dE.d\theta$ for four steps are increasing when alpha energy emitt

ed then each one changed. However, at $E_p=20$ MeV cascade double differential cross section $d^2\sigma/dE.d\theta$ not shown at angle 60.25° because all results are zero, the incident proton energy is smaller than target element, it has a large mass number.

On the other hand, as a result in CEM03.1 code for $p + {}_{90}\text{Th}^{232}$ at $E_p=360$ MeV in this reaction (α, n, p) produced has been made for compared total double differential cross section $d^2\sigma/dE.d\theta$ at angles $\theta= (0^\circ, 20^\circ, 40^\circ, 60^\circ)$ respectively.

In the alpha energy emitted, as can be seen in Figure 4.9 when total double differential cross section $d^2\sigma/dE.d\theta$ at the beginning of the curve for all angles at 360 MeV are increasing with increases alpha energy emitted then they are decreasing.

However, for neutron energy emitted in Figure 4.10 total double differential cross section in the same incident energy and angles are decreasing sharply with increases neutron energy emitted. In the last case for this reaction in the same incident energy but in emitted proton energy shows in Figure 4.11 at the beginning of the curve total cross section are increasing sharply but when the curve bring to the peack then total cross section $d^2\sigma/dE.d\theta$ decreasing.

Likewise, for $p + {}_5\text{B}^{10}$ reaction make for several energy ranges and various angles, in these reactions neutron energy emitted for all interactions with out at $E_p=660$ MeV, in this reaction alpha energy emitted and produced has been made for four steps (Total, Cascade, Precompound, Evaporation) at angle $\theta= 90^\circ$. As can be seen in Figure 4.24 total and evaporation are equivalent but cascade cross section increasing and decreasing alternately.

Otherwise, for $p + {}_5\text{B}^{10}$ reaction at all energy range with all various angles precompound did not show, because all results are zero and the incident proton energy is largest than target element, it has a small mass number. As a result in CEM03.1 code for $p + {}_5\text{B}^{10}$ at $E_p=186$ MeV in this reaction (α, n, p) produced has been made for compared total double differential cross section $d^2\sigma/dE.d\theta$ at angles $\theta= (0^\circ, 20^\circ, 40^\circ, 60^\circ)$ respectively.

In the alpha energy emitted, as can be seen in Figure 4.26 when total double differential cross section $d^2\sigma/dE.d\theta$ at the beginning of the curve for all angles at 186 MeV are increasing with increases alpha energy emitted until bring to the highest then they are decreasing sharply.

While, for neutron and proton energy emitted are similar but in proton energy emitted at beginning of the curve total double differential cross section $d^2\sigma/dE.d\theta$ increases with increases proton energy emitted. Overall, all results of CEM03.1 are compared to experimental values and they are in good agreement with the measurements at all energy ranges except for $E_p=360$ MeV with angle $\theta=22^\circ$. This is because the program is not duplication the output or consequence at occasionally, CEM03.1 code has a special method.

CURRICULUM VITAE

Fulname: Majd Hamad SMAIL

Gender: Male

Martial: Married

Date of birth: 11.7.1981

Birth place: Erbeel

Nationality: IRAQ

Address : www.majed.hamad@ymail.com

Telephon No. : 009647504705378 _ 009647507221270

I was born in 1981. I was graduated from the University of Salahaddin faculty of Education department of physics production in 2004. I enrolled at the postgraduate programme in Bingol University Institute of Science Department of physics in 2016, and finished my research in 2018.
